Project Gutenberg Collection

Contents — Volume 5

1. Scientific feeding — Dora C. C. L. Roper [2025]
2. Constipation and its correction by exercise — C. O. Benson [2025]
3. Untitled — Thomas Cradock Hepworth [2025]
4. The slide rule — Charles N. Pickworth [2025]
5. Untitled — William H. Burr [2025]
6. The book of wonders — Unknown [2025]
7. The decay and the restoration of civilization — Albert Schweitzer [2025]
8. A text-book of veterinary anatomy — T. Swann HardingThe Project Gutenberg eBook of The truth about the tobaccoThe Project Gutenberg eBook of A text-book of veterinary anatomy [2025]
9. Minerals in rock sections — Lea McIlvaine Luquer [2025]
10. Rethinking Indigenous Religious Traditions with Jace Weaver — 'noil' [2025]
11. The book of the cat — Frances Simpson [2025]
12. Genius rewarded — John Scott [2025]
13. Untitled — Edward Mahon Wev [2025]
14. Some points in choosing textiles — Charlotte M. Gibbs [2025]
15. Untitled — Unknown [2025]
16. Untitled — Morris Fishbein [2025]
17. Untitled — Unknown [2025]
18. Arts and crafts of old Japan — Max Simon Nordau [2025]
19. The watchmakers' hand book — Claudius Saunier [2025]
20. Untitled — Anonymous [2025]
21. How and what to grow in a kitchen garden of one acre — E. D. Darlington [2025]
22. The laws of contrast of colour — M. E. Chevreul [2025]
23. Aeolus; or, the future of the flying machine — Major Oliver Stewart [2025]
24. The organisation of thought, educational and scientific — Alfred North Whitehead [2025]
25. Untitled — Bolton Hall [2025]
26. An idea that saved a business — Leonard Dreyfuss [2025]
27. The wilderness — Amy E. Mack [2025]
28. The Russian road to China — Jr. Lindon Bates [2025]

Introduction 7

Preface 9

PART I.

Chapter I. Food. Classification and Function of Foods 13

Chapter II. Study of Foods 16

PART II.

Preparation of Foods.

Table of Measures and Weights 43

Chapter I. Green Vegetables 43

Chapter II. Legumes and Meats 43

Chapter III. Fish, Cheese and Eggs 57-64

Chapter IV. Soups 67

Chapter V. Cereals, Noodles and Dumplings 76

Chapter VI. Breads, Cakes and Puddings 84

Chapter VII. Sauces and Salad Dressings 98

Chapter VIII. Salads 104

Chapter IX. Gelatines and Toasts 111

Chapter X. Fruits, Puddings and Gruels 119

Chapter XI. Fluids 129

PART III.

Chapter I. Food Requirements.

Table of Food Requirements 139

Chapter I. 15 Sample Menus with caloric value for the average adult.--Food for the Aged, giving 12 Sample Menus with caloric value 140-146

Chapter II. Diet during Pregnancy 150

Chapter III. Care and Feeding of Children, including Recipes and Menus for Infants; Menus for the Second Period; Menus for the Third Period; Wrong and Right Management 153

[Illustration]

[Illustration]

Chapter IV. Light Lunches for School Children. Nut Foods and Sandwiches 168

Chapter V. Table of Food Combinations. 143 Menus for Breakfast. What shall we Drink for our Meals? 172

Chapter VI. 168 Menus for Dinner 177

Chapter VII. 76 Menus for Supper 185

Chapter VIII. Poor Man’s Bill of Fare, including: Sample Menus for one day. Bookkeeping. Menus for 56 days, with calculations as how to feed a Family of Five (2 adults and 3 children) on $3.50 per week and on $5.00 per week 189

Menus for Thanksgiving week 213

Mixed Boiled Dinners 214

PART IV.

Disease: Prevention and Treatment.

Chapter I. Constipation. Malaria. Suggestions for Chronic Invalids. Tuberculosis. Prevention of Tuberculosis. The House we live in. Treatment of Tuberculosis. Rickets. Obesity 218

Chapter II. Care and Feeding of Convalescents. Vomiting. Diet. Suggestive Menus. Additional Menus with caloric value 228

Table of Foods with caloric value 242

APPENDIX.

Chapter I. Mental Hygiene and Diet. The Immigrant. Health Hints for Busy People 245

Chapter II. Hygiene Economy and Sanitation. Preservation of Eggs. Dishwashing. Disinfection 251

Table

Giving average composition of common American food products 262

INTRODUCTORY NOTE TO SECOND EDITION

Before the manuscript for the first edition of “Scientific Feeding” went to the press, it was reviewed by several presidents of Mothers’ Clubs and other women organizations; they realized that it would fill a long-felt want in the home and a large number of advance subscriptions were sent in.

After publication the gratifying demand for this work necessitated the preparation of a second edition within a month.

DORA C. C. L. ROPER, D. O.

INTRODUCTION

This is a practical and hygienic cook book for all who consider life and health valuable. Intelligent homekeepers, nurses, managers of institutions and factories, all who are interested in furnishing the most nutritious food at the least cost, or wish to distribute such a work, will find this book worth its weight in gold.

After twenty years of persistent study, combined with praccal work as nurse and physician in private and in institutions, beginning in Germany, I am able to-day to present this valuable work, and hope that it may be placed in the hands of every home-maker in the country. It is designed for the purpose of modifying the cost of living and of eliminating, to some degree, the hardships and drudgeries of our women. It is excellent for school feeding, and presents the keynote to health and longevity, helping to prevent mental, physical, and moral diseases.

The great facilities for research work in the modern laboratory offer a wide field for the study of preventive medicine and hygiene. The world is beginning to recognize the fact that a large number of diseases are the result of wrong conditions. Improper eating, drinking, sleeping, unsuitable work, excess of amusement, and wrong educational systems are to blame for a large number of germ diseases and chronic ailments.

The body is the temple of the soul, therefore the laws of hygiene (concerning our internal and external body) are divine. Many of the orthodox teachings and divine laws in reference to hygiene, fasting, and feeding are a safe guide for the prevention of disease.

It has been my object to present a practical and sane method of living, free from fads and the teachings of one-sided extremists. All natural foods are wholesome, if properly combined, prepared, proportioned, and selected with care to agree with the temperament, environment, age and climatic conditions. I have devoted a special chapter to economical menus for people of moderate means, and have endeavored to show how it is possible to feed a family of five on a moderate sum, without injury to health. The amount of food and the proportions agree with what is demanded by modern standard dietaries.

A large number of cook books have been written during the last one hundred years to tickle the palate. Much valuable time has been wasted and many innocent victims have paid the price for the sins of gluttony, caused by modern methods of living.

The most learned and advanced thinkers are turning their attention more and more to scientific dietetics. The question of feeding is one of the most important subjects our present generation has to deal with. It is my desire that this book may contribute to this cause, and that it may awaken thousands of mothers and daughters to appreciation of the dignity and importance of their life work.

PREFACE

The human body is a wonderfully complex and mysterious establishment, presided over by life. It is composed of the dust of the earth, organized by creative power.

The elements composing the human body are: Oxygen, hydrogen, carbon, nitrogen, chlorine, sulphur, phosphorus, fluorine, calcium, natrium, magnesium, silicon, iron and potassium.

Our bodies are maintained by food, air, light, activity, rest and sleep.

The union of oxygen with one or more of these elements is called oxidation. If the process of oxidation within our bodies goes on rapidly we feel warm and energetic; if it goes on slowly, the degree of heat and energy is less; in fever there is rapid oxidation; in people who suffer with chronic diseases there is incomplete and slow oxidation.

In order to produce harmony between the elements in the body, it is not only necessary to breathe pure air, and eat wholesome foods, but it is equally important to have those food elements, which are taken into our body, selected in the right quantity, quality and combination. It is further necessary to have them prepared in the mouth by mastication and insalivation. If this is done, the chemical affinity or combining power of the foods is satisfied, and digestion, absorption, sanguification, circulation, oxidation, assimilation, excretion and clorification will go on perfectly.

In order to keep our bodies in perfect health, we must understand their laws. The structures and functions of the body are intimately connected, and one is dependent upon the other.

Life at the beginning is a tiny cell; as it multiplies into other cells, it forms blood vessels, nerves, muscles, bones, lungs, liver, brain, heart, and stomach, until the body is completed. The growth of the body is from within, before and after birth. The natural food for the infant is mother's milk, the next best is the milk of a wet-nurse, whose child is about the same age as the one to be nursed. Artificial preparations of milk from a cow, goat or donkey is the next best.

The appearance of the teeth indicates that the feeding of solid food can be begun. The kind of food required for the child as well as for the adult differs with different individuals. A normal and healthy mother will be directed by her instincts, reason and judgment to choose the right food for herself as well as for her infant.

An old saying goes, "God created foods, the devil created the cooks." A few thousand years ago, when the art of cooking was in its infancy, physicians and surgeons were not in such demand as to-day. The preparation of foods for the average household in those days consisted mainly of boiled cereals prepared with salt and water, boiled and roasted meats, and baked breads. Such articles, if eaten in proper combination with raw fruits, greens, and nuts, will keep the appetite at the normal state. The principal victims of disease in those days were the kings, the idle rich and the very poor. Since civilization has progressed, and the rights of man are more equalized, the whole race is in danger of degeneration through the invention of fashionable and artificially prepared foods.

In this age of refinement, our teeth, which were made to last as long as our bodies, begin to decay before we are matured. Foods are ingested into our bodies instead of being digested. Public hygienists and technical bacteriologists work hard, trying to prevent such diseases as diphtheria, scarlet fever, tuberculosis, typhoid fever, and many other infectious and epidemic diseases, resulting from unclean food and water, and imperfect sewage systems.

Even with the purest of milk, meat, and water, we can make a filthy garbage can of our intestinal tract by the ingestion of foods which do not harmonize chemically, the result being decomposition. Right here we have all the dangers of modern diseases and pus formation, resulting in appendicitis, phlebitis, ovaritis, cancer, Bright's disease, and all the above mentioned diseases, without having to look further for the garbage can on the back porch or the sewage system in the yard. The waste products from our tables, and the excretions from our bodies would be less dangerous to health if the selection, combination, and preparation of our food were more natural. The excretions of properly fed animals are not so dangerous to our health; why should ours be?

The hygienic rules as taught by the orthodox Jew in reference to the combination and preparation of foods are wise. He is not allowed to mix milk and meat, meat and fish, and many other articles of food which do not combine well chemically. The Jewish methods of killing animals and the preliminary preparations--such as the watering and salting of meats before cooking--are also more hygienic. They eliminate part of the toxins of the meat, which have been in close contact with the air.

Since life and personal health are generally in charge of woman, the right place for every girl under eighteen or twenty years is at home or in school. No young girl under this age should be allowed to enter a profession, workshop, or business college. An occupation which by long hours of work over-develops a certain set of muscles and nerves before maturity, will produce an abnormal development and an unstable temperament. Co-education at this age is also harmful, the result being premature development, and elopement marriages, or arrested sexual development and extreme independence, or marriage and continual suffering, owing to physical defects and lack of knowledge of the care of the human body, and of domestic science.

Every woman is a born nurse. How valuable would it be, then, to give every young girl, beginning at the age of twelve, a rudimentary course in nursing and in the care of children; in the art of selecting, combining, and preparing foods; and in the art of housekeeping. An industrial high school course with such technical work as is suitable for woman's sensitive brain would develop her brain and body in every direction and make the future woman a healthy mother of healthy offspring. Those muscles and nerve centers which have been well developed during puberty will be the strongest throughout life.

The store, the factory, the office, and the business college are no places for a girl under twenty years of age. If for some reason she has no desire to follow her natural calling in life, there will be plenty of time to prepare herself for other work after the age of twenty.

If a law could be enforced to compel every woman to present a certificate of health and maturity, and a diploma of qualification when applying for a marriage license, much unnecessary misery, disease, and many untimely deaths could be avoided.

The feeding as well as the mental, moral and physical training of children is the natural profession for women. Children have in them all the possibilities for good and evil. Mistakes during this period will affect the child throughout its life. Thousands of infants and young children are killed every year by wrong feeding and environment. A large percentage of brilliant and exceptional children fill the jails and insane asylums. Idleness, stupidity, and criminal tendencies are =diseases=, and =diseases can be avoided by right living=. Children with hereditary weaknesses require double care and attention; but remember the wonderful law of nature works always toward the normal; the good tends to overcome the bad.

If the brain of a child becomes starved by the use of sweet-meats, and clogged by the use of rich condiments and highly seasoned food, or by an excess of starchy foods, there is always great danger, and more so, if the child is exceptionally bright and active. A large amount of arterial blood is sent to the brain, and if this blood contains much waste matter, the eliminating organs will soon be overworked and all kinds of diseases are liable to follow, such as brain fever, softening and subluxation of bones, epilepsy, chorea, meningitis, paralysis, tuberculosis of the lungs, bones, and mesentery.

Many young women who, through wrong food, environment and unsuitable educational systems, have dwarfed their bodies, find motherhood a great burden. They have to pay the penalty for the sin that is committed on them. Their children will not be so strong, and will have less resisting power, and their grandchildren, if there be any, will land in the institutions for the incurable, if the careless feeding and wrong habits are kept up by each succeeding generation. On the other hand, if the progress of degeneration is checked by right living, the work and time invested will be well repaid during one generation.

PART ONE

CHAPTER I.

"THE BLOOD IS THE LIFE."

Its Structure and Function Depend on the Building Material.

Foods are substances which, when introduced into the system, supply the necessary material for growth, renewal and maintenance of the vital structures. Food is anything that nourishes.

Foods must contain the same elements found in our bodies. The body requires a combination of different food elements in proper proportion to produce a suitable diet. Foods are divided into five classes: water, protein, fats, carbohydrates and mineral matters.

Air and sun are also foods, but are not generally spoken of as nutrient.

WATER.

Our bodies consist of about two-thirds water. It helps to regulate the body processes, and supplies building material. Watery fruits and vegetables contain pure distilled water. The amount of water required for the average individual differs greatly. If water is added to our foods in the cooking process, a lesser amount is required for drinking. Wholesome, non-stimulating food will call for a normal supply of water between meals.

PROTEINS.

These are sometimes called albumen, and they supply the body with nitrogen, sulphur and phosphorus. They are great tissue builders; they also furnish energy and heat, in combination with fats and carbohydrates.

Sources of Proteins:

Legumes, lean meats, nuts, cheese, whites of eggs, fish, and the glutens of the grains. Milk contains proteins in the right proportion with fats and sugars to make it suitable as a food for infants. Oats, wheat, and rye contain more protein than other grains, and if no other protein foods are on hand, these can maintain health for a long time without harm. (For combinations, see introduction of "Poor Man's Bill of Fare.")

FATS.

They are obtained from the vegetable and animal kingdoms. They supply heat and energy in the most concentrated form, and are also flesh-builders. In diseased conditions, where economy of nerve force is required, fats in combination with acids, minerals and gelatine can form a substitute for part of the protein foods.

CARBOHYDRATES.

These are found in large percentage in cereals and in fruits which contain stones and seeds, and in underground vegetables, including the lighter starches, such as sago, agar agar, sea moss and gum. Milk can serve as a carbohydrate for special conditions; being evenly proportioned with fats and protein it contains little waste. A certain amount of carbohydrate foods in the form of cereals is necessary in our daily diet, as they are rich in lime and fat--yielding material which is required for ligamentous and other elastic tissue. People who live on fruits, greens and nuts, or on fruits, greens and meats only, require a larger amount of protein food, in order to make up for the loss of cereals.

MINERAL MATTER.

In an organic form, we find mineral matter in large proportions in green leaf vegetables, small fruits and berries, bran, rye, green peas, string beans, tomatoes, yolks of eggs and in all the outer skins of legumes, grains and fruits. The importance of the mineral elements in our foods has been little understood, so far. Of late, health reformers are beginning to realize that many serious diseases, such as tuberculosis, insanity and malnutrition, are the result of mineral starvation. Three-fourths of these valuable minerals are removed from our foods daily by modern milling, bleaching, and polishing of rice, wheat, corn and all the other grains. Not alone the minerals, but necessary volatile oils, acids, and ferments are removed by these processes. Refined white flour and sugar have been on the market for the last hundred years; and much time and health have been wasted with the writing of fashionable cook books, and the manufacture of anemic snow white cakes, crackers, biscuits and soft putrefying puddings and desserts, prepared with skim milk, sugar and eggs. The deficiency of minerals in these products has created an abnormal desire for salts, spices, and chemically pure sugar, followed by an additional craving for intoxicating beverages and liquors. The latter articles cannot enter into the composition of perfect teeth and bone, or gray nervous tissue; therefore, the result is premature death and many new diseases.

It is my desire to present in this book such food combinations as perfect as can be produced from food material with our present methods of milling and preliminary treatment. Many people have become so delicate in structure that they cannot use coarse breads and cereals; therefore, a variety of different cereal foods have been included. Vegetable foods, such as are rich in minerals, have been added to the breakfast foods in place of sugar and beverages. In order to supply the body with the necessary amount of minerals, we must learn, to eat greens for breakfast, until our so-called breakfast foods have improved in quality.

All foods possess potential or latent energy. The sun is the great positive element, and plants store up the sun's energy. It is transferred to us through the eating of plants and animal foods. Through the process of oxidation this energy is set free in our bodies, and appears as heat and muscular power. This energy contained in foods is known as heat or fuel value, and is expressed in terms of a heat unit or calorie. A calorie is the amount of heat necessary to raise one kilogram of water, one degree centigrade. This is spoken of as a large calorie, which is used in determining the energy value of food. The small calorie is ¹⁄■■■■ of a large calorie.

The physiological fuel and energy value of the different foods is as follows:

1 gram of Protein yields 4 Calories 1 gram of Fat yields 9 Calories 1 gram of Carbohydrates yields 4 Calories

To determine the energy value of a food or combination of foods it is necessary to know first its composition. Then determine the weight of protein, fat, and carbohydrate in grams and multiply these weights accordingly.

CHAPTER II.

STUDY OF FOODS.

The average homekeeper knows little of the nutritive value and chemical composition of the food she buys. The desire to tickle the palate enters more into the selection of food than reason or judgment. Others, who have studied along certain lines without the fundamental training for this work, often make greater mistakes in the selection and combination of foods than if they had not studied the subject at all.

It is not sufficient to know just which foods are suitable to the individual and which are harmful; it is necessary to have a fairly well balanced diet which contains the correct proportions of protein and non-protein elements.

The following pages present briefs on the value and chemical nature of different foods not mentioned in recipes:

VEGETABLE FOODS.

These are divided into several classes. They are: Legumes, cereals, roots, bulbs, tubers, leaf, flower and fruit vegetables. All plants are made up of a mass of cells, each consisting of a membranous wall, enclosing a gelatinous mass, in which lie imbedded the nucleus or center of cell activity and minute grains of starch or other material which the plant has manufactured.

In young plants these cell walls are called cellulose; later wood cells begin to develop. The wood cells grow into fibrous material, called woody fibre. In poorly grown or stale vegetables this woody tissue becomes very hard and thick, and therefore is indigestible. For this reason it is best that all green vegetables are grown quickly and eaten while they are fresh. When fresh they will snap crisply. Peas, green corn and string beans will cook in one-third of the time if used directly after gathering, instead of being kept for several days before using.

THE LEGUMES.

The legumes are rich in vegetable protein, and differ from flesh foods on account of being richer in protein and minerals and less stimulating. They are free from animal intoxication.

DRIED PEAS.

Green peas are richer in minerals than yellow peas, beans or lentils, the protein being in the form of legumin and easier to digest. They are very purifying and should be eaten freely, especially during the cold winter or rainy season. They are a suitable food for the brain-worker as well as for the muscular-worker, and can be prepared in many different ways. Yellow peas are an excellent food for muscular-workers.

DRIED BEANS.

They contain more of the protein than peas, lentils or beef. They are therefore a very rich food and should not be consumed in large quantities. The brown, red, and black beans are richer in iron and minerals, and are therefore more suitable in cold weather. The hulls of all legumes are difficult to digest, therefore it is important to soak legumes before cooking. In countries where the water is hard, it is well to have soft water on hand for the cooking of legumes. If rain water cannot be obtained, boil a kettle of water each day and set aside to cool for cooking purposes. Legumes may be soaked with hot or cold water. Green lima beans should be put to cook in boiling water without soaking, like all green vegetables.

LENTILS.

They are rich in iron and should be used freely in cold weather. Boiled onions are a good addition, in place of fat meat.

GREEN PEAS AND BEANS.

Green peas differ from other green vegetables. They are richer in protein and can serve as a meat substitute during the summer. String-beans resemble the green leaf vegetables in their composition, but do not contain sufficient protein to serve as a meat substitute. They are very purifying to the liver and intestines, and should be eaten freely by people of a bilious temperament.

CABBAGE.

Cabbage is rich in minerals. It can be made very indigestible by careless preparation. Raw cabbage is easily digested if chopped very fine and mixed with grated potato and mayonnaise dressing. Cooked cabbage should be treated with acid and mixed with the yolk of an egg if it disagrees. Some people prefer sprouts to cabbage. They resemble each other very much in composition. Cabbage contains more water and cellulose. It is best to use only the innermost part of cabbage, if it disagrees.

CAULIFLOWER.

This belongs to the cabbage family. It is rich in sulphur and is one of the most easily digested vegetables, if properly prepared. If it disagrees, treat it with acid or serve it for breakfast instead of for dinner.

CELERY.

Celery contains valuable minerals and is soothing to the nervous system. Celery roots are rich in fat and a healing food for people with kidney, liver, and intestinal trouble. The green stalks of celery root should never be thrown away. They can be tied into a bunch and cooked with soups of meat or legumes. Celery is a very valuable food for people with a bilious temperament.

ASPARAGUS.

This is an easily digested vegetable and resembles celery. As a food for medicinal purposes it may be eaten raw or cooked.

CARROTS AND PARSNIPS.

They resemble each other, carrots being richer in sugar; the parsnip contains a little gluten. They may be eaten in the raw state with good effect.

TURNIPS.

Turnips contain some valuable minerals, but being rich in sugar and water, they are liable to ferment in weak stomachs, especially if eaten with lean meats, white breads or other foods, which are poor in fat. They should not be eaten in the middle of the day by people who do active work. If they disagree at night, they may be eaten for breakfast in combination with fat meats or stale bread and butter. Yellow turnips are richer in nutriment than white turnips. Raw turnips are wholesome if they agree. Never combine turnips with other starchy foods at the same meal, such as potatoes, rice, white flour preparations, apples or cucumbers.

CORN.

Green corn is rich in fat and protein, and can form a perfect meal during the summer if combined with tomatoes. Do not cook the corn if it is agreeable raw. Canned corn should be used with care for people with intestinal weaknesses. If used for soups it should be strained and diluted with an equal amount of hot water before thickening.

TOMATO.

The tomato stimulates peristalsis and is a wonderful tonic for the liver. It is one of the most perfect fruits, rich in oxalic acid and iron, and unsurpassed as a medicinal food. It contains a vegetable calomel and serves as a purifier for the liver in bilious conditions. It can be prepared and combined in many different ways. It may be one of the first articles given to a patient after an operation, serving as a food and tonic; it counteracts the sweetish taste of the chloroform and prevents fatty degeneration of the liver.

Whether a food is eaten raw or cooked it is important that it be ripe. (Not ripened on the market.) For people with weak digestive organs, the best way to serve tomatoes is in the form of sterilized strained juice over toast in combination with milk or in the form of soup from canned strained tomatoes. The theory that tomatoes are liable to produce cancer is entirely unfounded. Any kind of food if eaten in excess and wrongly combined will aid in the progress of disease, but all natural foods rightly combined are wholesome if eaten according to needs of the individual.

Tomatoes combine well with fatty foods,--eggs, cheese, meats and fish.

LETTUCE.

This is the most desirable greens on our tables and combines well with almost any kind of food. Being rich in minerals and alkaloidal extracts, it tends to render the digestive fluids alkaline and promotes oxidation and nutrition. If lettuce is eaten in proper proportion with other foods at the morning or noon meal, it has a sedative effect and keeps an excitable constitution better balanced throughout the day. People with delicate stomachs should not eat lettuce at the evening meal. All raw salads prepared from greens and super-acid fruits are best eaten at the beginning of the meal, or with the meat dish at the morning or noon meal.

CUCUMBERS.

They are a valuable food and should be eaten almost daily by growing children and anemic people, especially if much muscular work is required. The cucumber is considered an indigestible article of food by people with perverted appetites. The way in which the cucumber is usually prepared in the average household renders it unfit to eat. The extraction of the natural juice and the treatment with salt make the cucumber tough and indigestible, and, if eaten in combination with half a dozen other articles, it produces indigestion. Cucumbers should never be eaten at night.

NUTS.

Nuts are high in nutritive value, and are better evenly combined with non-protein elements than flesh foods are. They are rich in fat and minerals, and form an ideal diet in combination with raw fruits and greens. They are not sufficiently appreciated as a food, and receive much unjust criticism as to their digestibility. All nuts are wholesome. The right combination and proportion, and the time of day when eaten, are of great importance. The kind of activity as well as individual peculiarities have much to do with likes and dislikes or requirements of certain foods.

ALMONDS AND BRAZIL NUTS.

These nuts feed the higher nerve centers and generate a high quality of intelligence.

WALNUTS, PINE KERNELS AND CHESTNUTS.

These are excellent for those who wish to put on flesh. Care must be taken not to overtax the liver. People who have been accustomed to a large amount of bread or other starchy foods should begin with a small amount, and substitute them for bread. If they disagree, use lemon, cranberries, oranges or fruit salads with them. Walnuts supply the larger nerve structures. They are well balanced in all the elements and are excellent for people doing hard, muscular work. Sweet dried fruits also form a good combination with nuts. Chestnuts resemble cereals on account of being rich in starch. They contain less protein, fat and minerals than other nuts, and therefore combine well with such foods as supply these elements. Baked and boiled chestnuts are generally more agreeable than raw ones. Pine nuts are rich in both protein and fat.

COCOANUTS.

They are rich in starch and fat and resemble the cereals closely.

HAZELNUTS.

They are a valuable food, but require thorough mastication.

THE PEANUT.

The peanut is a very nutritious nut, but rather difficult of digestion for some people. It resembles beans and peas, and is sometimes classed as a legume. Excess of nuts at one meal, or nuts which have been poorly masticated, may cause severe disturbances of the liver and stomach. If the teeth are poor, the nuts may be ground, but even then great care must be exercised to insure their proper insalivation. Cooked nut foods and all vegetarian dishes to which strained legumes, nut-butter, eggs and other rich foods are added, should not be indulged in by people with weak stomachs.

NUT-BUTTER.

Great care should be exercised in the preparation of foods with nut-butter. Never spread it on bread without first diluting it with an equal amount of water. Do not keep it on the shelf like ordinary butter after it has been mixed with water; prepare only sufficient to last for twenty-four hours, and keep it on ice.

FRUITS.

There are three classes of fruit: acid, sub-acid, and sweet fruits.

Fresh raw fruits, if eaten in the right proportion with other articles, are wholesome. The habit of eating a large amount of acid fruits at the beginning of the morning meal is not necessary. If a heavy meal is eaten in the evening, remaining half digested in the stomach over night and putrefying, then acid fruits will cleanse the stomach in the morning. The better way is to go to bed with an empty stomach and there will be no need of cleansing in the morning. People of a highly nervous temperament should not eat the very sweet fruits at the morning or noon meal, as at this time they are too stimulating.

Hot house fruits out of season are health destroying. Certain fruits, such as apples, plums, tomatoes, apricots, grapes, figs, bananas and cranberries, will keep for a long time in the natural state, if properly preserved. Some of them can be dried and used in the winter. Fresh fancy summer fruits are not required during the winter by healthy individuals, neither are canned fruits, jams or jellies.

The canning of fruits during hot summer days is a health destroying occupation and a waste of time and money. Fresh fruits prepared with a large amount of water and sugar are little better than beer, wine and whiskey. If such fruits are eaten with yeast bread, potatoes and a variety of other foodstuffs, they set up fermentation and burden the eliminating organs. A few jars of sterilized fruit juice should be prepared and kept on hand for medicinal purposes only.

Fruits are an important article of diet, but few people know how to use them wisely. A large percentage of deaths in young children is due directly to the wrong use of fruits. Many forms of infantile paralysis, intestinal disease and malnutrition in general are due to the lack of knowledge of the scientific combination of fruits with other articles of food, so as to furnish a wholesome meal.

Many teachers of Domestic Science and writers in monthly magazines seem to have forgotten, entirely of what an ordinary mixed diet should consist. Their bills-of-fare are becoming more complex all the time. We find combinations, such as banana fritters, custard, meat, potatoes, nuts, milk, biscuits, dates, several kinds of vegetables, puddings, cheese, coffee, cake and ice cream, suggested for =one meal= (sometimes less, other times more than this). Any intelligent, thinking person must realize that such a mixture, besides being a great waste, will turn the stomach of the strongest individual into a yeast pot. Those with strong eliminating organs, who take plenty of out-door exercise and recreation of some kind, may be able to throw off the excess of poison for a long period, while others endowed with less vigor will suffer from the effects within a short time.

People who live on cooked foods consisting mainly of meat, bread, sugar, soups, puddings, cooked cereals, milk, etc., should realize that they have already filled their systems with foods which contain a large amount of water, and therefore will overburden their intestines and kidneys by adding a liberal amount of fruits to such a dietary. There is always great danger of fermentation and putrefaction, especially if constipation sets in, and here we have all the dangers of modern diseases, which begin with mal-nutrition, be it from under-or over-feeding. Only the most perfect specimens of men and women are safe from danger. Why? Because their instincts lead them to choose the right articles in the right combination, and at the table they know “when to stop,” while an individual with weak sensory nerves does not feel the effects of satisfaction from the food until dullness, pain or discomfort appear. It is from this latter class mostly, that we have our health reformers, while the former class with their perfect battery, which can turn the poorest food materials into first grade tissue, look on us as diet cranks and faddists.

The man who ate three square meals all his life, indulged in tea, coffee, liquor and tobacco, was never sick and lived to be 100 years old, probably could have lengthened his years to 300, had he not been so dangerously strong.

The menus suggested in this book are made up carefully and scientifically, so that each individual can easily find a diet suited to his temperament, environment, age and occupation. Nuts contain a high percentage of protein, and therefore form an ideal dietary in combination with fruits. Meats, eggs, cheese, cream and fish are the next best articles suitable to combine with fruits; raw greens are an excellent addition, but breads, puddings, sugars, beverages, mushes and cooked vegetables are better left out at a meal if an abundance of fruits are taken, especially at dinner, or the amount of watery foods taken into the body during twenty-four hours will not be in the proper proportion to the solids. Dry legumes are very rich in protein, but being dissolved with water during the

cooking process are less suited to combine with raw fruits, especially for those suffering with flatulence or kidney disorders. Apples, tomatoes and vegetables combine best with legumes. Apples and tomatoes, being of the most perfect type of foods, combine well with all classes of protein foods, including cereals. They should be staple articles in every household. As to other fruit combinations, study recipes and menus, and keep in mind that no matter how valuable an article may be, excess is a poison.

Those who live mainly upon dry foods, such as uncooked cereals and nuts, can safely make their morning and evening meal of fruits alone, while others who live like the average, if they attempt to make a meal of fruits alone, and continue to do active work, will soon fail in health.

BERRIES.

All berries are rich in minerals and feed the brain cells. They contain traces of protein. Blackberries and huckleberries are rich in volatile oils and iron, and are of great medicinal value. They are excellent for the evening meal in the form of gruels and drinks.

People with digestive troubles should be careful in combining raw blackberries with other foods. They are rich in protein and may take the place of part of the meat dish on hot summer days. They should never be used as a dessert after a heavy meal.

STRAWBERRIES.

Strawberries are the first fruit to make their appearance in the spring. They are rich in iron and valuable acids. As they are in season for a long time they should not be eaten to excess, never more than once per day. From three to eight ounces, according to age, is sufficient for one meal. If perfectly fresh, they combine well with fresh cream or milk. Yeast bread, red meats or legumes should not be eaten at the same meal with strawberries. Berries which have undergone slight decomposition should be placed in a mason fruit jar with a little water and be sterilized. This juice will keep for several days in a cold place and can be used for the flavoring of milk, or for softening zwieback which is to be served with cream or milk. If the juice has undergone fermentation reboil it before using. It may be used for fruit puddings or fruit gruels or be mixed with other fruit juices. In this way everything is utilized and nothing wasted.

CHERRIES.

The cherry season is short. Therefore, they should be eaten almost daily. All varieties are wholesome. If desired, several kinds may be mixed at one meal. They combine well with egg foods, whole wheat, cornmeal and fish. They may be eaten at the beginning or at the end of a meal or by themselves. People with weak stomachs should not eat them at night.

BLACKBERRIES.

They are a valuable and nutritious fruit and can form a perfect meal in combination with light cereal foods. They have little preservative properties and therefore should be eaten only when perfectly fresh. For young children or people with intestinal weakness, only the juice should be used in the form of wine or gruels.

RASPBERRIES.

They are a light and delicious fruit. They combine well with milk, egg foods, or nuts, and can be served morning, noon or night.

PEACHES, PEARS AND APRICOTS.

They are all three rich in sugar and cellulose, and can form a substitute for part of the cereal foods during hot summer days. (See recipes for Salads.)

THE PINEAPPLE.

The pineapple contains bromaline and is of medicinal value in the treatment of certain stomach disorders. It is not a necessary article for the table of people of moderate means.

BANANAS.

They are a very nutritious fruit and can partially replace the cereals. If combined with green leaves, and lemon, they can form a perfect meal. The bitter substance which is contained in the inner skin of the banana should be scraped off with a knife and added

to the bulk, as it counteracts the sweet flavor of the banana and adds to its digestibility. Baked bananas are not necessary for a healthy stomach.

APPLES.

They are among the most perfect of fruits. People who have difficulty in digesting a sufficient amount of cereals should eat apples almost daily. If raw apples disagree, they can be made agreeable by combining them with fat meats or oil in the form of a salad. Baked apples and apple sauce are also good, provided they are not spoiled with too much sugar. Some apples are fibrous and muscle-feeding; others are richer in phosphates and valuable minerals. For salads use tart apples.

GRAPES.

Grapes are a valuable fruit for the table if eaten in the right proportion with other foods which contain fat and protein. They are rich in sugar and tartaric acid. As a medicinal fruit they may be eaten in large quantities by themselves.

NECTARINES.

Like the pineapple, they belong to the luxurious fruits and are adapted for people with a large purse. They are rich in sugar and starch, with a small amount of cellulose.

ORANGES, GRAPEFRUIT, LEMONS AND LIMES.

They all belong to the citric acid group, and are of all the fruits, the richest in valuable acids, which in the process of digestion are converted into salts, rendering the blood more alkaline. The latter three should be used in greater quantities in countries near the coast or in low and damp districts, especially during the rainy season. The outer skin is rich in volatile oils and is useful in the preparation of fruit-and-milk soups. The white rind is useful as a medicine, for patients who suffer from malaria. A small amount of it chewed while sipping a glass of fresh milk will greatly add to the digestibility of the milk and serve as a germicide to the liver. The juice of one-quarter of a lemon may be taken in connection with the skin of one-half a lemon, in combination with a glass of milk. During fever, the skin should be carefully expectorated.

FRUIT JELLIES.

If prepared from fruit juice and cane sugar only, they are powerful stimulants and have little food value, for the reason that they arouse the nerve cells to extreme activity and rapid oxidation. They furnish no food for the nerve cells, and the nutritious elements in the other food materials taken in combination with these jellies pass out of the body without being assimilated, or produce congestion and inflammatory conditions. Even natural stimulants, in the form of raw fruits, can become harmful if taken, in excess, or in the wrong combinations, unsuitable to the individual requirements. If the glycogen-making function of the liver becomes overburdened, the result will be diabetes, neuralgia or starch-poison.

COMPOTES OR STEWED FRUITS.

They are more wholesome and economical than jams and jellies, which are prepared with large amounts of sugar.

They are best served with the meat dish or with some substantial pudding. If served with sponge cake at the end of a meal, the digestive juice becomes acid, and produces fermentation and mal-nutrition.

PLUMS.

Green, red and blue plums are all valuable fruits. The blue plum is rich in iron, minerals, and sugar, and is, next to apples and tomatoes, one of the most perfect fruits. It has great preserving qualities and if picked on a dry, sunny day and placed carefully in straw in a dry, cold place, will keep until Christmas. For combination, see menus and salads.

People who have distress from eating raw plums should let them alone or eat them in the dried state only.

FIGS AND DATES.

They have an average of thirty per cent water, are rich in sugar and contain some protein and saline matter. They are an excellent food for people who are fond of sweets. They are more wholesome than canned summer fruits. However, they should not be

indulged in during hot summer days, or in the spring time when the brain needs relaxation.

THE WATERMELON.

This is the largest of the melon fruits, containing sugar, salts, cellulose and distilled water. It is an excellent food during hot weather. People who suffer from chronic kidney disorders should only indulge in it in small quantities at a time, and never combine it with mushy or other starchy foods. A few drops of lemon is a good addition, in place of free salt.

MUSKMELON.

This fruit is also rich in sugar and cellulose. What has been said of watermelon in reference to combination also applies to this fruit.

CRANBERRIES.

Cranberries, like gooseberries, currants and lemons, are purifying to the blood and very valuable as a food in malarial districts. Cranberries combine well with oatmeal, cornmeal, pork, chicken, turkey and veal. Use no more sugar for the preparation than is absolutely necessary to counteract the tart taste. Cranberry jelly prepared with pure sugar is unwholesome. Raw cranberries and raw celery are a good combination for salad.

CEREALS.

Cereals are the most perfect products of the vegetable kingdom, and make fairly well balanced foods. They are deficient in fat, with the exception of corn and oats. In the processes of milling and cooking, cereals have been more abused than any other foods, by depriving them of their valuable minerals, and by compounding them into soft putrefying puddings or rich cakes. Concentrated or predigested cereals, as advertised under the name of breakfast foods, cannot take the place of ordinary rolled, whole, or steel cut cereals; they have lost valuable salts and lime during the process of baking and they also deprive the walls of the stomach of the normal stimulus, which is necessary for thorough utilization.

Well boiled cereal foods in the form of dumplings, macaroni, noodles or whole cereals are stimulating and heating to the whole alimentary tract, they take longer to digest, and are more thoroughly utilized by the system. Predigested cereals and zwieback are more suitable for the evening meal, or at the end of the noon meal, when the body has expended energy. Shredded wheat and zwieback may be used with benefit for breakfast, if a sufficient amount of raw fruits or greens is eaten with them, but if they are used in combination with other predigested foods, such as milk or sugar, it gives the intestine nothing to do. For the evening meal, toasted breads and cereals combine well with such foods as supply the lack of lime, fats and minerals: cream, fruit-gruels, yolks of eggs, gelatine, sago, milk and green foods.

WHEAT.

Wheat can be used the year around. In cooking cereals it is very important to start with the right quantity of water, and allow each starch granule to burst by fast boiling during the first twenty or thirty minutes. After this, let it cook slowly for twenty or thirty minutes longer, or until it is done. It is not necessary to cook cereals for several hours in order to make them fit for the human stomach. If well boiled cereals disagree, they are generally poorly prepared and allowed to get pasty before the starch granules have burst, or else they are combined with raw sugar and cream, which produces fermentation.

RYE.

Rye is richer in minerals and contains less starch than wheat. It is not superior to wheat, but it is one of the oldest and most perfect foods, and is the staff of life to some of the healthiest and strongest races of the old world. It is laxative, and because of this it is more suitable for certain individuals than for others. Rye is a good winter food; during the summer we have many valuable berries which supply the system with certain minerals, therefore we require less of rye bread, or rye preparations, during this time of the year.

Rye combines well with all starchy fruits and vegetables, which are deficient in minerals, such as potatoes, pumpkins, squash, melons, turnips, carrots, beets, bananas, cucumbers, rice and corn. It also combines well with sweet fruits. Apples, pork, veal, lamb, cheese, eggs, cream, milk, bacon and oily foods are all good additions to rye. Boiled rye and starchy foods are unsuitable combinations.

Whole rye or wheat bread should never be eaten fresh. It should be kept in a bread box, with good ventilation, in a dry place, or near the stove. Sun dried bread is the best.

OATS.

Oats are rich in fat and lime, and like wheat and rye belong to the most perfect foods. A fireless cooker is a convenient apparatus for the preparation of oats and wheat. They should be thoroughly cooked for at least half an hour before setting them into the fireless cooker.

RICE.

Rice, although low in protein and fat, is one of the most easily digested of all cereals, and is especially suitable for brain workers and people of sedentary habits. This book contains a large number of different recipes for the preparation of rice.

SAGO AND TAPIOCA.

They are manufactured from certain palms and roots, and belong to the lighter forms of cereals. They are easily digested if soaked for several hours before cooking, and can be partially substituted for the heavier cereals. Cornstarch, arrowroot, potato-flour and agar agar belong to the same class. They are all valuable for the sick and for young children.

BARLEY.

Barley is also rich in lime; it should take a more prominent place among food substances than it does. Pearl barley should be soaked with soft water before cooking. If it is to be strained, mash it up thoroughly with a potato masher, and pour more boiling water over it after the first liquid is strained off.

ANIMAL FOODS.

EGGS.

Eggs contain all the elements necessary for the building up of a young animal; they also contain all the elements which can be found in the human body. The eggs of hens are used most commonly. The chemical combination of the whole egg and that of the brain and nervous system have much in common. The white of the egg contains about eighty per cent water, twelve of albumen, a small amount of fat and some salts. For medicinal purposes, eggs should be fresh, directly from the nest. Eggs are deficient in minerals and should be combined with foods which are rich in minerals.

CHEESE.

Cheese is one of the most economical and nutritious of foods, and a true meat substitute. To serve cheese after a dinner is a wasteful extravagance, and dangerous to health. Cheese combines well with bread, macaroni, potato and other cereals; raw greens are also a good addition. Cooking or baking cheese makes it indigestible. Grated or sliced is the best way to serve it. People who have difficulty in digesting cheese should always combine it with raw apples, onions, or tomatoes and lettuce, in the form of a salad. If it still disagrees, leave out the cereals entirely at the meal, or use black bread with it. A combination of cheese, eggs and milk in the form of a Welsh rarebit makes a heavy and indigestible meal, and should only be indulged in by people who are very strong, and exercise a great deal out of doors.

MEAT.

People who live almost entirely on cooked foodstuffs and white flour bread, find meat a necessary article of food, and consume it in larger quantities than would be necessary, if whole wheat bread and raw fruits and greens were used. Under the present systems of forced and improper feeding of animals, and the preservation of meats by cold storage, flesh foods are becoming more dangerous. There is no need for such an excess in the production of meat, except to satisfy our habits. If human beings and animals are fed by force, they are not healthy. Flesh, eggs and milk from animals which are fed by force, are unwholesome and inferior in quality.

Under certain conditions and in cold climates, meat is a necessity, therefore the feeding of animals should be under the observation of health officers. We need quality more than quantity.

Pork, although condemned by many people as unfit for food, is a wholesome article, if the animal is fed upon dry, substantial food. Pork requires a longer time to digest than other meat, and therefore it should not be eaten at the evening meal. Pork was considered as an unclean food by the ancient Jews; perhaps the reason for this was that the Jew's system did not require pork, because of his constitution and the climatic conditions. Fat pork is a specific food for the kidneys; it is less stimulating and easier to oxidize than any other meat.

Beef is perhaps the most economical meat for family use. A good quality of meat should contain both fat and lean. All meats should be well soaked and washed before cooking. Cold meats are sometimes more agreeable than hot meats.

Veal, lamb, chicken and game are all wholesome meats if eaten in moderation and at the right time of the year. Fresh meats should not be served oftener than once per day, or better still, three times per week. The internal organs and glands, such as the lungs, liver, kidneys, tongue and stomach, are very nutritious. Sausages, if prepared from fresh, clean meat, and not highly seasoned, are cheaper and more nourishing than canned meats, and often preferable to fresh meat, which has hung a long time in a meat shop. The internal organs contain much lime and organic salts, as they feed the glands of the body; they should be well soaked before cooking, in order to drain the thick and impure blood out of them.

Beefsteak, chops and roasts should be slightly salted before they are cooked. Free salt sprinkled on meat, or other dry foods, before serving, is injurious to the lining of the stomach and blood vessels; lemon can be used instead. Many people have an abnormal craving for salt. This is a symptom of anemia; the system lacks minerals. The only way to supply the necessary elements is by taking salt in the organized state in raw greens and fruits. Free salt can satisfy such craving temporarily, but it creates an abnormal thirst. Raw apples, tomatoes and all other acid fruits, in combination with greens, are the best additions to meats.

FISH.

Fish is a valuable article of food. It is less stimulating than lean meat, and easier to digest and oxidize; for this reason it can be recommended for brain workers. It contains a large amount of phosphorus and nitrogen, and if properly combined with foods which are rich in minerals, such as apples, tomatoes, lemons and greens, fish is quickly utilized. Fish and whole rye bread is also an excellent combination. Fish being soft, it is necessary that it be thoroughly masticated. Fish can become very dangerous as a food when not fresh.

MILK.

Milk is found indispensable in some cases of sickness, especially in fevers. The greatest care should be exercised in getting clean, fresh and perfect milk, and in keeping it in a cold, clean atmosphere after delivery. Milk may be given as a food, raw, boiled, sterilized, pasteurized, or peptonized, and can be modified with water or other foods in many different ways. The best and most suitable method of preparing it for the patient must be left to the attending physician.

The color of perfect milk is yellowish white, =not blue white=. Its odor is pleasant. A drop of milk poured into a glass of fresh water will go to the bottom if it is good milk. In order to ascertain if the milk is alkaline, neutral or acid, put a small piece of red litmus paper into it, and if it turns strongly blue the milk is alkaline. If a blue litmus paper turns strongly red, the milk is acid. Perfect milk should be neutral or slightly alkaline. After the milk has stood for several hours it gradually becomes more acid.

Milk which is acid in reaction, or blue in color, is unfit as a food for children and invalids. If a mother is uncertain as to the quality of the milk she is feeding her child, she should have it examined by the city chemist.

Milk, even if handled very carefully, contains many germs. Therefore, on hot days it is better to sterilize the milk for an infant, even if the child is in perfect health, or able to take raw milk. If the milk can be obtained directly from the cow two or three times per day, it may be given raw on those occasions. If it has stood a little while, it may be heated quickly to 155 degrees F. over a hot fire, while stirring it.

CERTIFIED MILK.

This is a high grade of sanitary milk which comes from special dairies, where great care is taken to keep everything in perfect sanitary condition. The cows are kept in perfect health and are fed upon food which produces milk perfect in composition. There are, however, milkmen who have principle enough to supply their customers with milk of good character and perhaps of as high a grade as that from inspected dairies.

I have, in my practice, often come in contact with people who were informed by their milkmen that certified milk required no boiling or sterilization. Some people are impressed with the idea that certified milk has already undergone some sort of preparation. The fact that in these days milk laboratories can be found in many large cities, may easily bring confusion of mind as to “what the milk is certified for,” especially to those who are not acquainted with the preparation of milk and do not know the difference between raw and sterilized milk, if they buy it. Such instructions should be given by better authorities than those who deliver milk, or the label should state “what the milk is certified for.” Certified, or any other raw milk, which is over eight hours old, is not a fit food for infants.

BOILED MILK AND CREAM FOR TABLE USE.

Put the desired amount of milk or cream, or mixed milk and cream, into a clean saucepan, stir over a hot fire until it reaches the boiling point or to about 200°F. Then pour into a pitcher and set in a pan of cold water; stir until the milk is cold. Set on ice or in a cold place for 24 hours. Milk prepared in this way is the only wholesome kind to use in addition to boiled cereals and fruit puddings. It is also often preferable to raw cream and milk, in combination with raw fruits. If the milk is to be used on cereals for the morning meal, it can be reheated or used directly after boiling. If hot milk is added to cereals, the sugar will not be missed.

If boiled milk or cream has stood for 24 hours it has become unfit for further use unless it is reboiled. If putrefaction has set in, boiled milk can become more dangerous as a food than raw milk which has stood for the same length of time; therefore careful handling of boiled milk as well as other boiled foods is of the utmost importance. (See Chapter on Hygiene and Economy, under Left-Overs.)

In many foreign countries it is a general custom in every household to boil milk directly after delivery, for the infant as well as for table use. To do differently means uncleanliness. Modern invention of coolers and ice-boxes in every house, and delivery of milk in bottles, has gradually done away with this custom. Many of our present generation of house-wives are so little acquainted with practical housekeeping that they consider food fit for use as long as it has not soured, notwithstanding the many changes it has undergone on the pantry shelf. Raw cream is fit for use only directly after it has left the separator. Raw milk should not be considered fresh and wholesome for table use longer than eight or ten hours after milking, and then only with the most careful handling. Following this precaution, morning milk, which is delivered during the day, should not be used raw later than five or six o’clock in the evening. Remember that all milk begins to turn acid as soon as it comes in contact with the air. The longer it stands the more acid it will be, besides being laden with germs. The process of cooking or scalding raw milk checks the fermenting processes and renders the food more alkaline, especially if it is to be taken with cereals or fruit puddings and gelatines.

Cooked milk is not a natural food, but neither are cooked cereals. Raw milk is quickly digested, while boiled milk takes several hours to digest, and so do boiled cereals. A combination of raw milk, or cream, and cooked cereals will force the stomach to absorb the milk immediately, while the remainder, poorly masticated and filled with germs, will tend to produce an acid process rather than an alkaline. If sugar is added to raw milk and cereals, the process of intestinal fermentation is complete. If the glandular system and the eliminating organs are strong, they will work harder in order to rid the system of this excess of acid; but if the constitution is not able to stand the strain of wasteful nervous expenditure, discomfort and disease will be the result! Enlarged tonsils are often the first sign of danger. We cannot invent customs of feeding that interfere with natural laws without paying the penalty.

MISCELLANEOUS FOODS.

FATS.

Fats are derived from the animal and vegetable kingdom; they are rich in carbon and hydrogen, but poor in oxygen. Emulsified fats are present in cream, nuts and the yolks of eggs. Oleins are mainly found in oils obtained from fruits, nuts and vegetables. Butter contains mainly palmitin. Suet, from beef and mutton, consists of stearin and palmitin. Lecithin is found in yolks of eggs and in some nuts; it is a highly complex compound, and a food for the brain and nerve substance. Suet and mutton fat contain much stearin, and are harder to digest by some people than other fats. However, the digestibility of a food depends much upon the individual requirements, and a little self study will soon convince each what forms of fat are best suited to his needs. As a rule, people of large bone structures require a greater amount of fat in their food than those not so constructed.

Fats are changed into fatty acids and glycerine by the secretion of the bile and pancreatic juice, and in combination with the intestinal juices form soluble soaps. In acute diseases fats should be taken only in the form of butter, milk, or cream, in limited quantities. Fatty foods are beneficial for children suffering with scrofula or rickets, and in all chronic, wasting diseases.

People who do much indoor work, or those who are not able to digest a sufficient amount of protein or cereals, require more fats. The latter can be made easily digestible if rightly combined and prepared in the form of soups, warm sauces, boiled custards and mayonnaise dressing. In this way the fat globules are equally divided in the food and can be better emulsified than if eaten in the solid form, or in combination with white bread or other unsuitable articles. Cream, and the lighter nuts, combine well with sweet foods, while oils, yolks of eggs, meat fats, and solid fats, combine well with foods which are rich in minerals and oxygen.

People who are unable to furnish their table with expensive fats, such as butter, olives, cream, olive oil, bacon, eggs, eel and other delicacies, should use the cheaper forms of fats, as corn, oats, herring, walnuts, cream-cheese, cottonseed oil, bran, leaf lard, vegetable butter, middle rib of beef, blood and liver sausages. Meat products, prepared from the internal organs of the animal, are rich in lime and fat, and, if prepared from fresh meats of healthy animals, they are often preferable to canned and cold storage products, or to meat which hangs in a meat-shop for a week. However, every one who buys these articles should investigate the source and manner of preparation for himself.

SUGAR.

Artificial sugar is not a necessary article of food for the healthy individual who is able to supply his body with fresh and dried fruits the year round.

True candies are: figs, dates, raisins and other tropical fruits. The delicious summer fruits are better eaten without sugar. Undoubtedly nature did not mean for us to indulge in sweets during hot days, or she would have provided us more plentifully with them. All the spring fruits are tart: people who wish to improve the taste of berries add sugar to them at the expense of health. Our forefathers, who did not enjoy such luxuries, had better health than our present generation. The sugar-cane in its natural state is a valuable food. It contains gluten and minerals, such as are found in other vegetables, and if eaten in this form it is more wholesome than refined sugar. The gluten and minerals are destroyed by chemical processes which are necessary to produce sugar from the cane and beet. Pure, crystalized sugar cannot sustain life, unless it is eaten in the proper proportion, with foods which contain gluten, minerals and fats.

Sugar which contains minerals cannot crystalize; it remains syrup, therefore the latter is more wholesome than sugar. In order to produce beets, which are richer in sugar and poorer in salts, certain methods of manuring are employed. The profit gained by this method is a financial one. The consumer is the loser.

If artificial sugar is united with cocoa or other bitter, sour, nutritious substances it will serve as a food; therefore, sugar in the form of a prepared food such as chocolate, gelatine and gruels is wholesome for those who require cooked foods. If the sugar industry were diminished, the canning and stewing of fruits would also be diminished, and we would have fewer tea and coffee drunkards. All this gluttony in stimulating beverages and sweet fruit sauces was not indulged in by the masses a hundred years ago, therefore the constitution of the average individual at that time was much stronger.

Many parents are impressed with the idea that their children require a large amount of sweets, in order to make them grow. We cannot force nature without paying the penalty. At maturity, we reap what has been sown for us, or what we have sown for ourselves.

SPICES.

Spices are a species of aromatic vegetables and fruits used for the seasoning and preservation of foods. Their flavor is pleasant and stimulating to the mucous membrane of the mouth.

The odoriferous substances yielded from these plants are: the volatile oils and ethers of peppermint, roses, orange flower, lavender, camphor, lemon, bitter almond, wintergreen, cinnamon, cloves and a number of others. They are used for perfumes, medicines, confections, and in the art of cookery. Many of the spices used for food are dried, as bay leaves, thyme, marjoram, vanilla beans, dried skins of lemons and oranges. Ground spices or liquid extracts should be used sparingly. Many of them are adulterated. Free salt and ground spices create an abnormal desire for water and food, and they injure the mucous membrane lining of the blood vessels and glandular structures, and obstruct the capillaries.

People who cannot relish their food without these artificial appetizers should fast a while, or replace them by natural stimulants, as tomatoes, apples, lemons and greens. Few people realize the harm that is done by the number of salt, sugar and pepper holders that are placed on the table at every meal, to say nothing of the dozens of boxes of ground spices that fill the kitchen shelf. A pinch

of pepper on gravies, milk soups, or other nutritious dishes, if mixed thoroughly with the food, assists in the coagulation of soft nitrogenous foods and prevents putrefaction, but excess of it, or if sprinkled on dry food, is very harmful.

The best way to use spices is to buy them whole, in the fresh or dried state, and chop, grate, or grind them when needed. Vanilla beans, bitter almonds, bay leaves, cinnamon bark and many others may be used whole and removed before serving.

Children's food should never be covered with pepper or other stimulating spices. Under our present system of living salt has become a necessary adjunct to our food. Legumes, cereals or any other foods which require a large amount of water for cooking need an additional amount of salt. It should be added before the food is removed from the fire, so that the salt will be properly dissolved and combined with the food. Moderate amounts of preserved, salted meats and fish are valuable as antiseptics, if combined with soft, cooked, nutritious foods in the form of soups and gravies, or with milk foods, eggs, cereals or legumes. Salt used in this way will not hurt the lining of the alimentary tract and other tissues, as free salt does when it is sprinkled on lettuce, meat, potatoes or other dry food. Never use salted, smoked or preserved meats or fish in excess. If possible, investigate the source and manner of preparation of preserved foods.

DESSERTS.

Desserts have only been mentioned in the form of steamed puddings, gelatines, oranges, grapes or bread and butter in combination with black unsweetened coffee. Artificially prepared desserts in the form of attractive, soft puddings and other rich mixtures flatter the palate and renew the appetite. The true enjoyment of eating is in the satisfaction of hunger. The craving for desserts indicates a desire to stimulate certain nerves, which force the contents of the stomach into the intestine and destroy the digestive processes or produce decomposition, hasten absorption, and exhilarate the brain with the toxins hereby produced.

Those who desire to correct the habits of intoxication in themselves or in others should consider whether the abnormal craving is for merely physical pleasure or for the satisfaction of starved and overworked brains and bodies, and the change should be brought about accordingly. To drop a long acquired habit at once may prove harmless to one person and very fatal to another.

The worn-out digestive organs need to be toned up and developed gradually, either by stimulating fruits or fruit juices or by tonics in the form of bran-tea and malt-coffee.

People who have vigorous appetites and strong digestive organs may eat a few nuts at the end of the meal until the appetite has been restored to normal. For those who like sweets, a large number of recipes have been given for fruit salads and light cooked dishes. Many can be served as whole meals for the evening, or in combination with milk broths or soups.

MUFFINS AND PANCAKES.

Many people who find pancakes indigestible will do well to observe the time when they are most agreeable. If they are made with eggs, cream, and water, or with rich milk, and properly prepared and combined with suitable articles, they are generally agreeable to the most sensitive stomach.

People of sedentary habits, or those who do brain work mainly, should not eat pancakes or muffins for breakfast.

All ingredients, as well as the vessel, should be cold. The batter should also be made in a cold place or out of doors. The oven, the baking pans and the oil in which the cakes are baked, should be as hot as possible.

BREAD.

Bread made from white flour and yeast is the staff of death. Few people realize that if they wish to use white bread as a food the proper amount of minerals, fats and nitrogen must be added, in order to make it a perfect food. Yeast bread, if eaten with jams and jellies in large quantities between meals, is health destroying and dwarfs the body. It is also unwise to eat white bread in combination with other starches, as rice, potatoes and soft puddings. The average individual who takes plenty of out-door exercise may get along well for years on such mixtures and suffer no inconvenience, but people with poor eliminating organs or chronic ailments, or those who do much indoor work, do well to use yeast bread in moderation, especially if prepared from white flour.

Baked and boiled cereals are more nutritious than bread. In the fermenting process which takes place in rising bread, valuable substances such as lime and salts are lost. It is rendered more acid, and therefore unfit as a food for people with weak stomachs. If yeast bread is combined with foods which render the fluids of the stomach alkaline, it is less harmful.

SOUPS.

Many American housekeepers do not know how to prepare soups and do not like them. The fact that people of many nations in the old world, with smaller incomes than the average American working man, use soups daily, once or twice, and are far superior in physical strength and endurance to the latter, who lives mainly on beefsteak, white bread, potatoes, sugar, tea and coffee, should convince every one that nutritious soups are an important article of diet. Close study and persistent effort will enable every homekeeper with small means to learn how to prepare a soup that is palatable and nutritious. The daily use of white bread and butter is expensive. Besides it produces diseases, imperfect bodies and premature old age.

All who are in the habit of eating more than their systems require and especially those who indulge in large amounts of bread at dinner, would do well to begin their meal with a soup. Legume and cream soups will furnish a satisfactory meal by themselves. For combinations, see “Menus.”

PART TWO

PREPARATION OF FOODS.

TABLE OF MEASURES AND WEIGHTS.

A standard measuring cup contains 8 ounces or ½■ pint.

1 tablespoon = 3 teaspoons 2 tablespoons = 1 ounce 8 tablespoons = 4 ounces or ½■ cup 16 tablespoons = 8 ounces or 1 cup

All ingredients measured by the cup, tablespoon or teaspoon are measured level.

1 pound (English weight) = 425 grams or 16 ounces 1 pound (Metric system) = 500 ” 2 pounds (Metric system) = 1000 ”

CHAPTER I.

GREEN VEGETABLES.

Green vegetables furnish a large amount of easily digested carbohydrates and contain much mineral matter in which meats and cereals are deficient. That they add to the highest purity of our blood has been proven by the fact that many blood and skin diseases have been cured by the application of specific greens alone. However, no matter how valuable an article is, it should be used according to the needs of the individual. As vegetables also contain a large amount of water, it is not wise for one who has to perform active mental or physical labor to indulge in a large amount of cooked, especially underground, vegetables at the noon meal. At this time of the day the system requires the most nutritious foods in the form of proteid elements, no matter whether the meal consists of cooked food, cold or warmed over. Green peas and corn are best eaten at the noon meal, as they are rich in proteid elements. Asparagus, tomatoes, string beans and leaf greens are also suitable at this time of the day, provided some nutritious food of the proteid class is served with them. For further combinations, see “Left Overs” and Menus.

The blanching of vegetables, as advised by some authorities, will always remove valuable constituents of the plant. The blanching and ventilation of vegetables during the process of cooking is advised, in order to make them more wholesome. All artificially prepared foods will lose certain constituents through the process of cooking, and this loss is generally made up by additional flavoring or sauces. Vegetables which are cooked in very little water and kept well covered (not ventilated), will lose less of their natural qualities, and the injurious gases which do not escape by this process can be made harmless through the addition of fats, in the emulsified form, as sauces, the yolk of an egg, lemon or cream.

In the consumption of food, as well as the custom of dress and education, some people have reached that stage of refinement where degeneration begins. We cannot refine natural food without paying the penalty for it, which means the producing of disease and the shortening of life. The excessive use of refined sugar, alcohol and other artificial stimulants, has produced a dislike for fatty foods by many people, so that they refuse to eat sauces, or fat meats in any form, the only fat they use being butter. While the latter is a valuable food, it often cannot be assimilated by the system if spread on white bread, or mixed with cooked vegetables; it generally serves only as a lubricant. If butter is eaten in excess, especially in the summer, it clogs the system. Some people prepare vegetables and soups with melted butter for the sake of convenience. This is a waste, since a tablespoonful of butter or other fat properly emulsified as directed under butter sauces will often give more nutriment than one-quarter of a pound of butter

wasted by soaking into toast or other cooked foods.

The American method of cooking green vegetables in a large amount of water and throwing it away, then seasoning them with butter and spices and serving them with lean meat and white bread, produces a starvation diet. In such a meal, the important mineral matter and the fats in vegetables and whole wheat grains are left out, and are supplemented by an excess of starches and water in the form of bread, beverages and desserts. Additional fats should be added scientifically and combined with foods which are rich in minerals and acids.

All vegetable water, especially that of canned or sterilized fruits and vegetables, is very wholesome and antiseptic. Strained, sterilized tomato, currant, gooseberry and strawberry juices are unsurpassed as a liver medicine in some conditions. These same foods will lose their medicinal value if stewed in an open kettle. They should be prepared in Mason jars or cans. After opening, these fruit juices may be kept in earthenware on ice for twelve hours, and served again. After this they should be reboiled or sterilized, in order to check fermentation. For the sick, the same precaution should be taken with keeping fruit juices as with milk.

When using canned vegetables, never throw away the water, if it is not to be used for dressing. Add it to soups or use it in place of beverages. Pea, bean and asparagus water may be made very palatable if cream is added. See preparation of legume teas under “Fluids.”

In preparing vegetables for the sick, the finest of all dressings is the yolk of an egg and lemon juice, with a small amount of butter. The fat in the yolk of the egg being emulsified in a perfectly natural state, it feeds the mucous membrane of the entire alimentary tract and blood vessels. Besides neutralizing the gas producing tendencies of the foods, it aids in the digestive and assimilating processes and feeds the nerve sheaths. In all chronic conditions, which are the result of hardening of the arteries, a large amount of the yolk of eggs, combined with lemon and oil, may be used. There are a few vegetables which do not combine well with the yolk of an egg, such as turnips, carrots, beets and onions. These contain a large amount of sulphur and iron, which is also found in the yolk of the egg. Fat meats are good additions to the last mentioned vegetables, except onions, which are rich in oil themselves. If underground vegetables are served in the form of purees, they should be mashed very fine or rubbed through a colander; the butter which is added should not be allowed to boil. Peas, beans, cauliflower and cabbage are most likely to disagree if served with butter only. Butter sauces, cream sauces, yolks of eggs and lemon are the best additions to make them agreeable.

Some people prefer vegetables cooked in oil. Those whose systems can digest a large amount of fat will find them agreeable.

ARTICHOKES.

Wash them thoroughly and remove the outside leaves. Drop into salted boiling water and cook for 20 or 30 minutes. Add a few drops of vinegar to the water while boiling. Serve warm with a white sauce or let cool and serve with French or mayonnaise dressing.

ASPARAGUS.

Wash and cut them into inch pieces until the hard part of the stem is reached. Boil them for 20 minutes, or until tender. Serve warm with butter, milk, cream, or egg sauce, or cold with French or mayonnaise dressing. The asparagus may be scraped and tied into bundles when boiling.

BEETS.

Remove the green tops and wash them carefully. Do not prick the skin, as the juice will then escape and injure the color as well as the flavor. Young beets will be tender in about one hour, older ones take two to three hours. When done, peel and slice. Serve with a butter or cream sauce, or plain, with butter and chopped parsley. For salad, cut into slices and pour over them boiling vinegar, diluted with one-half water. Add whole spices if desired.

MASHED BEETS.

Prepare like the above. When tender, peel and mash very fine with a potato masher, and add butter and a few drops of lemon juice.

BEET GREENS.

Wash the tops and boil in a very little water until tender. A small piece of salted or smoked lean meat may be boiled with them to give them a better flavor. Chop fine and flavor with butter and lemon juice. A brown butter sauce may be prepared from the water in which the greens have been boiled; when done mix with the finely chopped greens, and let it boil a second, and flavor with lemon.

ROASTED CARROTS.

Wash, scrape, and cut them lengthwise into halfs and quarters, then cut crosswise into inch pieces or smaller. Cover with boiling water and cook for 10 or 15 minutes, with a little salt. Drain off the water (add to soups); brown some fat and flour, add to it soup stock, whey or the water which was drained off, and roast the carrots in it until done. Cover them tightly and add more fluid while roasting, if necessary. Flavor with chopped parsley.

CARROT PUREE. No. 1.

Steam or cook the carrots with salt and as little water as possible. A small piece of lean bacon or cornbeef may be added for flavoring. When done, mash very fine with a potato masher. Flavor with butter and a little pepper and parsley or lemon.

CARROT PUREE. No. 2.

Prepare like the above, and add one potato to three medium-sized carrots. If the potatoes require less time to cook, add them when the carrots are half done. This preparation may be especially recommended for chronic invalids or for those who have a dislike for the sweet flavor of the vegetable.

CREAMED CARROTS. No. 1.

Cook like carrot puree. When tender, make a butter sauce with the water; add parsley and hot cream, if desired.

CREAMED CARROTS. No. 2.

Cook like number one, thicken with flour or corn starch, and add some hot cream and parsley. Serve, like soup or vegetables, for breakfast or supper, with dry whole wheat or black bread. Butter is not required at the meal if cream is used. If the butter and cream are emulsified as in sauces, they are more wholesome.

PEAS.

Wash the peas while in the pods, then shell. Boil the pods in a very little water for 15 minutes, then take out and put the peas to boil in the same water. Add a little salt and sugar when almost done. Prepare further like creamed carrots. Some people prefer them with no dressing except butter. Those who have difficulty in digesting starch and wish to cut out the bread at the meal may use sauces or cream dressings with their vegetables, especially in the winter.

MIXED PEAS AND CARROTS.

Put the peas on to boil, and when half done, add an equal amount of carrots which have been cut into half inch pieces. Prepare with a butter sauce like creamed carrots, and add chopped parsley. This will afford a perfect meal for dinner in spring or summer. A few bread or flour dumplings may be served with it. The latter should be cooked with the peas 10 minutes before serving. Salted or smoked meats give them a good flavor.

PEAS AND CODFISH (Saxon Dish).

Cook the peas with a very little water, and add meat broth while they are boiling. Boil some fresh codfish in a separate saucepan, and when done remove the skin and bones, cut into pieces and mix with the peas. Prepare a butter sauce from the liquid remaining on the peas. Carrots may be added.

PEAS WITH LAMB.

Boil the lamb with sufficient water to cover it. Add salt and onion. When half done, put it to boil with the peas, which should have been boiled with water in another saucepan for 10 minutes. When meat and peas are done, remove the fat, thicken with flour and add the pea water to make a butter sauce. Flavor with parsley. Use the meat broth for soup or add the yolk of an egg or two, and

serve in cups.

MIXED VEGETABLES (Leipsiger Dish).

Use asparagus tops, young French carrots, peas, and cauliflower. Cook each vegetable separately with salt, in as little water as possible. When done, drain the water from each and use for soup. Mix the different vegetables in one dish and pour browned butter over them. Serve with Lobster Curry. A butter sauce may be prepared from the vegetable water in place of brown butter. Bread or flour dumplings may be served with it. Lean meat is also a good combination.

CAULIFLOWER.

Cauliflower should be avoided by those who have delicate stomachs, at the evening meal. It should be perfectly fresh and put into salted water for an hour before cooking, in order to take out any hidden insects. It should be boiled 20 to 30 minutes; if steamed it takes a little longer. Flavor with salt and a little sugar while boiling. Serve with brown or melted butter and lemon, or prepare a butter sauce with soup stock and the yolk of an egg, or with cream. Season with pepper. Serve with chipped beef or grated cheese for breakfast, or with lean meat for dinner. Left over cauliflower may be baked in the oven with cheese or bread crumbs, and served for breakfast. Tomato sauce is also suitable as a dressing. Cold cheese is a better combination with the latter than cream sauce or baked cheese.

STRING BEANS.

They are very purifying and should be eaten often, by people of a bilious tendency. Select young string beans, pull off the string on each side and break in pieces an inch long. Boil in slightly salted water and prepare like green peas. They may be mixed with carrots. Ribs of beef or lamb can be cooked with them as described in recipe for peas. For other combinations, see “Boiled Mixed Dinners.”

SPINACH.

This is also a very valuable vegetable. Besides being rich in iron and phosphates, it is laxative, and excellent as a medicinal food for constipation. Wash it thoroughly. For a delicate stomach use the leaves only. Steep in as little water as possible, chop very fine or rub through a colander; season with pepper, salt, lemon and butter, or prepare with a brown or white butter sauce from soup stock, or spinach water. Gelatine may be used in place of soup stock by dissolving the gelatine in the vegetable water. Smoked or salted lean meat may be cooked with it for flavoring. Serve with eggs or lean meat.

SPINACH (Saxon Dish).

Boil in as little water as possible, and chop fine. Then chop fine some well watered salt herring or other salt fish. Prepare the spinach with a butter sauce made from soup stock, add the fish and serve on toast. Dried bread crumbs or browned flour mixed with butter, without the liquid, may be added to any of the green leaf vegetables.

MUSTARD GREENS.

Dandelions, yellow dock, horse radish tops and lettuce may be prepared in the same manner as spinach.

OKRA.

Wash and remove the stems. Boil in salted water for 40 or 50 minutes. Prepare with a butter or cream sauce.

STEWED CUCUMBERS.

Wash and peel them. Then cut into pieces and cook with as little water as possible, until tender. Serve with fish or lean meat for dinner, or with whole wheat or rye bread for breakfast.

CELERY ROOT.

Wash and boil the roots with the skins. When tender, peel them and cut into slices. Prepare with a butter sauce made with soup stock or serve with French dressing. Flavor with parsley.

BLACK CARROTS.

Wash and scrape. Boil in salt water to which a little vinegar has been added. Prepare with a butter sauce, or mash fine. Serve with tongue, croquettes or boiled beef.

EGG PLANT.

Cut in slices about an inch thick. Make a batter of eggs, salt and flour; dip the slices of egg plant in the batter, and fry in hot fat. Serve with lean meat, for dinner or supper, or serve with green salad for breakfast.

STUFFED GREEN PEPPERS.

Cut off the stem end and remove the seeds. Fill the peppers with a dressing such as is given in recipes for bread dumplings or meat croquettes. Place them in a baking dish with two tablespoonfuls of oil or fat; when brown add a little flour and some soup stock, cover the dish and bake in an oven for about 50 minutes. The inner part of the peppers may be mixed with the filling.

ONIONS.

For stewing use small or medium sized onions. Boil them in salt water, drain off the water and serve with butter and lemon, or prepare a butter or cream sauce. They are best eaten for breakfast or dinner with some salted meat, and wheat or rye bread.

RAW ONIONS.

People who like onions and find they disagree on account of the strong acids, should grate them and mix thoroughly with sauces, or French or mayonnaise dressing.

FRIED ONIONS.

Chop the onions very fine in a wooden bowl. Then heat some butter and oil and fry them until light brown and pour over steak or mix with potatoes.

PARSLEY.

Chop enough to last for several days. Melt some butter and add the parsley, and let boil up once. When cold put on ice. This saves time, though it is best to prepare the parsley fresh for each meal.

MUSHROOMS.

Wash and dry them, then roll in flour and fry in fat until brown. Add some soup stock and steep until done. Cover well. If the stock is too thin, add a little browned flour; season and serve on toast.

RED CABBAGE.

Wash and cut in quarters. Mince very fine and put on to boil in a little water; let it cook for 20 minutes in earthen ware, then add three to five ounces of fat or oil, some vinegar, sugar, salt and caraway seed. Let all cook for several hours. A few apples may be cooked with the cabbage and taken out when done. The latter may be served for breakfast. When the cabbage is done, thicken with browned flour and let cook 10 minutes longer. Onion may be added if desired. A piece of salt pork is also a good addition in place of oil.

WHITE CABBAGE. No. 1.

Prepare the same as red cabbage.

WHITE CABBAGE. No. 2.

Cut in quarters and boil in a little water with a small piece of lean salted smoked meat, or without meat. When tender, drain and serve with butter and the yolk of an egg and lemon, or with an egg sauce or tomato sauce.

SPROUTS.

Remove the outside leaves and put to boil in a little salt water. When tender, drain and season with butter and lemon. The yolk of an egg may be added. A butter or egg sauce is also good.

COOKED CORN.

Remove the leaves and put in cold salt water for 30 minutes. Then boil for 20 minutes. Corn is best when eaten raw. It is very nutritious and will afford a perfect meal during the summer with tomato salad and lettuce.

CANNED CORN.

Thicken the corn with flour and water. Add a small amount of hot cream and season with salt and pepper or a few spoonfuls of tomato juice. If no cream is desired, drain off the liquid and thicken like butter sauce. Canned corn, being a rich and soft food, should not be mixed with many other foods at the same meal. It is more suitable for the morning or noon meal than for supper.

KOHLRABI.

Peel, slice thin, and stew in a very little water. When nearly done, add some hot soup. Prepare with a butter sauce. Chop fine some green leaves of the plant previously boiled and add. Serve with boiled beef.

VEGETABLE OYSTER.

Wash, scrape and boil in salt water until tender--about 40 minutes. Prepare with butter, milk or cream sauce, or mash fine and fry like potato balls. Season with lemon or pepper.

TURNIP PUREE.

Prepare like carrot puree. Cook with as little water as possible.

ROASTED TURNIPS.

Prepare the same as roasted carrots. They combine well with mutton.

FRIED PARSNIPS.

Scrape, wash and cut in slices, lengthwise. Boil in salt water for 5 minutes, then drain and fry in smoking hot fat. They can be turned in batter if desired. They may be fried without cooking, like sweet potatoes.

KALE.

This is a desirable vegetable in cold weather. It is purifying and very valuable during the rainy season, in malarial districts. Remove the leaves from the stems, wash and boil in salt water, using as little water as possible. Chop very fine and prepare like spinach. A little smoked meat may be added.

SQUASH.

If young and tender it does not require peeling. Wash, cut into small pieces and steam. When done, mash fine and season with salt, pepper and cream, or butter, and a few drops of lemon. It may be cut in slices and fried in oil, or dipped in butter and fried like egg plant.

TOMATO PUREE.

Cut some fresh, firm tomatoes into several pieces. Cook in a double boiler with as little water as possible. Rub through a sieve with a spoon or potato masher. From 3 to 6 ounces of thick puree is sufficient at a meal, for the average adult. For medicinal purposes, tomatoes may be eaten in large quantities.

CANNED STEWED TOMATOES. No. 1.

They are more wholesome if not cooked. Place a can of tomatoes in hot water to heat, drain off the liquid, and serve with meat, fish, eggs or cheese. The liquid may be kept for soup.

STEWED TOMATOES. No. 2.

Heat a can of tomatoes, thicken with flour and water, and let boil 10 minutes. Add some butter and flavor with onion, and small amount of sugar if desired.

STEWED TOMATOES. No. 3.

Prepare as number two, thicken with bread or cracker crumbs, instead of flour.

STEWED TOMATOES. No. 4.

Heat a can of tomatoes. Then heat some butter and oil in a flat saucepan, thicken with mixed flour, flavor with onion, add the tomatoes gradually, and let boil a few minutes.

STUFFED TOMATOES.

Wash the tomatoes and cut off the upper part with a sharp knife. Scrape out the pulp and fill the tomatoes with cold chopped meat mixed with onion and mayonnaise dressing. Garnish with lettuce and serve with bread and butter, or as an entree.

SAUERKRAUT.

Wash the sauerkraut in cold water several times. People with sensitive stomachs should boil it for a short time. Then drain off the water and put on to boil again. If no meat is served with it, use a few tablespoons of oil, lard, butter, or goose fat. Add onions and a little sugar or some apples for flavoring. Cook from one to two hours. Then add a little flour dissolved in cold water, or two raw grated potatoes. Remove the apples before serving. The latter may be eaten for breakfast or supper. If the onions disagree, remove them before serving. Good combinations with sauerkraut are: Pea puree, pork, bacon, liver, liver-pudding, white fish, and oysters stewed or fried.

CABBAGE ROLLS.

Wash some large cabbage leaves. Fill them with finely chopped left-over meat, mixed with eggs. (See recipe for croquettes.) Then tie the rolls together with a string. Steam in a shallow dish with as little water as possible. Serve with an egg sauce. Flavor with mace.

POTATOES.

Potatoes consist mainly of starch and water. They are more expensive than wheat, rye, oats, barley and corn. They should not be eaten oftener than once a day, or better three times a week. People who do hard physical or mental work should not eat potatoes at the noon meal. Fat meats, eggs, fish and greens combine well with potatoes; if they are served with lean meat, some fatty substance in the form of butter, cream or gravy should be eaten with them. Fried potatoes are not wholesome. The best way to prepare them is to boil or bake them in the skins, or boil or mash them in cream or buttermilk.

POTATO SALAD.

Boil or steam some potatoes with their jackets on. When done, peel and slice them into a deep bowl while warm; then sprinkle over them a little salt, pepper, and finely chopped or grated onion, and pour over them some boiling hot vinegar diluted with one-half water and mixed with melted butter or oil. Cover with a saucer and shake well; let stand for twenty or thirty minutes. If there is too much liquid, pour off some and mix the remainder with mayonnaise dressing and chopped parsley, if desired.

SWEET POTATOES.

Boil the potatoes in the jackets, let cool, peel, slice, and fry in one-half butter and one-half oil. Serve with cranberry sauce, lettuce, and lean meat.

Sweet potatoes may be peeled and sliced in the raw state, and fried in half oil and half butter. Serve as above. They are very suitable for breakfast.

CREAMED POTATOES.

Select small potatoes and boil in the skins. Add some salt. When done, peel and cut into thin slices. Bring some milk to a boil, and thicken with corn starch dissolved in water, or prepare a butter sauce with butter, flour and milk. Add the potatoes and some finely chopped parsley. Serve with fish or salted preserved meat.

CRUST POTATOES.

Use small, imported German potatoes. Boil with the skins, peel and turn in yolk of eggs and rye nuts; fry in oil and butter. Serve with sprouts, or spinach and meat.

STEAMED POTATOES.

Peel small sized potatoes, wash and put into a steamer or colander. When done pour into a dish, and mix with chopped parsley and fresh butter. Serve with fish.

FRENCH FRIED POTATOES.

Peel and cut into long strips or thin slices. Put into salt water on ice for half an hour. Fry in boiling oil.

MASHED POTATOES.

Peel, wash, and boil or steam the potatoes; when done, mash fine, and add some hot cream or cold buttermilk, and a little salt, also a piece of butter.

MASHED SWEET POTATOES.

Prepare the same as white potatoes.

POTATO BALLS.

Beat 2 eggs with an egg beater, mix with one cup of left-over mashed potatoes, shape into balls and fry in hot fat. Serve with bacon, fish, or sausage, for breakfast.

POTATO PUDDING.

Prepare the same as potato balls. Put the mass into a pudding dish and cover with rye nuts, grated cheese, or a beaten egg mixed with rye nuts, and bake half an hour.

POTATO AND APPLE PUREE.

Prepare as for mashed potatoes. Use apple sauce in place of milk or cream, mix well and add a liberal piece of butter. Serve with sauer roast, veal cutlets or sausage. It is good for breakfast with bacon.

CHAPTER II.

LEGUMES AND MEATS.

BAKED BEANS.

Pick over the beans carefully, wash and soak them in soft water as directed in chapter on legumes. If the beans are to be cooked with fat, scald or parboil the meat first, add it to the beans after they have cooked for about an hour. If the beans require long cooking, take the meat out when it is tender. When the beans are tender, pour them into a bean-pot or round pan, cover the top with part of the fat meat cut into slices, or pour some cooking oil over the beans, and add a few whole onions. Bake for about an hour. Onions and fat meat eaten at the same meal are liable to disagree, therefore serve the onions at another time, or use them only for flavoring purposes.

BAKED LENTILS OR PEAS.

Prepare in the same manner as baked beans. They require less fat for cooking, and are more palatable if served without meat than are beans. Onions are rich in oil, therefore if plenty of onions are used, the meat is not missed so much. In cooking legumes, it is best not to add the salt until they are nearly done, because the salt hardens the water. If legumes are preferred cooked instead of baked, it is better to add a thickening of flour and butter before serving, otherwise they may produce flatulent dyspepsia.

Legumes lose their natural flavor and stimulus in the drying and soaking process, therefore they are not palatable or easy to digest without some form of fat and appetizing raw salad, which supplies the needed stimulant. Many people add sweets to legumes or make them more indigestible by adding ground nuts and other rich foods to them, as in many vegetarian dishes. Such foods are a dangerous burden to a weak stomach and liver. Heavy protein foods require an acid medium for proper digestion and utilization. If legumes are used in the form of soups and purees, nothing should be added but a little flour, dry toast, fats, or raw vegetables. If we wish to be strict vegetarians we must live upon raw foods. If we wish to live on cooked foods, a moderate amount of meat is necessary for most people.

LIMA BEANS. No. 1.

Soak some lima beans in soft water. Cook in a small amount of water with a little salt. When tender, dissolve some cornstarch with cold water and add to the beans; boil for 10 minutes, then add a few tablespoonsful of hot cream and remove from the fire. Flavor with chopped parsley, if desired. Serve with frankfurter or other lean, smoked meats. Mashed or raw carrots are also a good addition.

LIMA BEANS. No. 2.

Prepare like the foregoing. Drain off the water and add a piece of butter, the yolk of an egg, a little lemon juice and parsley, if desired.

LIMA BEANS. No. 3.

Prepare like the foregoing. Drain off the water and prepare a butter-sauce, mix with beans and serve plain, or add the yolk of an egg, a little lemon, and parsley.

PEA PUREE.

Soak ¾■ cup of dried green peas in soft water. Boil with I quart of water and 1 onion for about an hour. Bake in a bean-pot for 1½■ hours or longer; add more water if necessary. Keep the peas covered. When done run through a colander and add 1 teaspoonful of butter. This makes about ¾■ of a cup of puree. One-third of this portion is sufficient for a sick person or a young child. Serve on toast, or with raw carrots, or cold fat meat.

BEAN AND LENTIL PUREE.

Prepare and serve like the foregoing. A small veal or mutton bone may be boiled with it. The puree must not be greasy.

SOUR ROAST.

Let a quart or less of vinegar come to a boil, dilute it with one-half the amount of boiling water, add some bay leaves, cloves, whole pepper, onions, or any other flavoring, and pour over a piece of beef (rump piece) which has been slightly rubbed with salt. Let it stand for several days. Then take it out of the liquid, cover with bacon or suet, and put into hot fat. After it has roasted for a while, stir a large tablespoonful of flour into the fat, add some water, and the spiced herbs. Cover well, and let it roast two or three hours. Add water or buttermilk to the gravy, if desired. Serve with potato dumplings, lettuce and stewed prunes.

VEAL CUTLETS.

Sprinkle some lemon juice over the chops, then beat up several yolks of eggs, turn the chops in them, dip in rye nuts and fry in hot fat for ten minutes. Serve with lettuce and tomatoes, or with boiled potatoes, lettuce, stewed prunes or apple sauce.

CHICKEN IN GELATINE.

Put a small veal bone to boil with the chicken. When tender, take a part of the broth, add some vinegar to it, boil for ten minutes with onions and spiced herbs. Cut the chicken into pieces, place in a deep bowl, and pour the hot broth and vinegar over it. Cool and serve the next day. Use about ½■ cup of vinegar to 1 quart of broth.

Another way is to pour pure, hot vinegar over the meat in the bowl, let it stand an hour or longer, then pour off the vinegar, and pour enough broth on the meat to cover it. Meat preserved in this way will keep on ice or in a cool place for a week. The meat and gelatine may be brought to a boil again at the end of the week. This will preserve it for a longer time. Goose may be prepared in the same manner.

LAMB OR PORK IN GELATINE.

The loin is the best part for this purpose. Prepare with veal bone like chicken.

PORK CUTLETS.

Prepare the same as veal cutlets. Fry with plenty of onions.

KIDNEY HASH.

Put the kidney into cold water for an hour, then scald with boiling water and boil in the soup together with a soup bone. When done, mince fine and prepare with a brown flour gravy. Serve on toast.

TRIPE.

Cut into small pieces and boil with a very little water, and a pinch of salt. When done, add some sweet whey or tomato juice. Heat some butter or oil, thicken with flour and add the liquid gradually, as for butter sauce. Season with chopped parsley.

HAMBURG STEAK.

Grind some round steak in a meat grinder. Shape into flat cakes and fry in hot fat with plenty of onions. Turn from side to side while frying.

STEAMED LIVER.

Liver must be fresh in order to be wholesome. During hot weather it may become dangerous as a food after it is one day old. Remove the toxic blood by placing the liver in water or sour milk for one hour. Change the water several times. Then remove the skin and tie some bacon or suet over it. Roll in flour and steam in fat for 20 minutes. Then add sufficient boiling water to half cover the meat. Flavor with bay leaves, salt, pepper and plenty of onions, also add a little vinegar and sugar, and steam for about an hour. Keep the saucepan well covered. Serve with potatoes or with apple and lettuce salad. The gravy can be strained and used the next day for breakfast or supper. See recipe for flavoring of sauces.

HASH.

Chop fine any kind of left-over, cold meat. Mix with one-third portion of grated or mashed potatoes, and add plenty of finely chopped onion and parsley. Brown some flour and butter, add a little soup stock and mix with the meat. Cook and serve on toast or with salad of greens.

FRIED CALVES' LIVER.

Slice the liver and put in cold water or sour milk for at least an hour. Change the water several times, then dry the liver and fry on a hot, oiled skillet, with onions. Serve with a salad of apples and lettuce, with French or mayonnaise dressing.

TONGUE.

Soak the tongue over night in cold water. Boil from three to four hours and serve with dried mushrooms and brown flour gravy.

CROQUETTES.

Chop fine some left-over meat, mix with one-half or one-third dried bread-crumbs, a little salt, pepper and mace. Then add several beaten eggs, mix well, form into balls, roll in egg and cracker-crumbs, and fry in hot fat. Drain on paper or in a wire sieve.

TONGUE IN GELATINE.

Fresh left-over tongue may be kept for a while by preserving it in gelatine with veal bone.

BRAINS.

Brains are very nutritious, but they are not a wholesome food for people with chronic indigestion. They should be served on dry toast and eaten with sour salads of fruits and greens.

SALISBURY STEAK.

Secure some fresh, thick, sliced, round steak. Scrape, or grind in a meat-cutting machine, and mould into flat, round cakes. Have an iron spider very hot and oiled to prevent sticking. Lay the meat cake in, and turn from side to side till cooked sufficiently.

CREAMED CHIPPED BEEF.

Bring to a boil some soup stock from veal or mutton bone, thicken with cornstarch or white flour, boil 10 minutes, and add one-quarter or one-third part of hot cream. Cut or chop the dried beef fine, pour over it some boiling water, let stand a minute, then drain, and mix the beef with the cream gravy. Add a pinch of pepper, if desired. In place of cream, milk and butter may be substituted and prepared like butter sauce.

BREADED GOOSE.

Use goose which has been cooked in sour gelatine. Take the pieces out of the bowl and warm in order to remove the gelatine. Then beat up several yolks of eggs, turn the meat in it, then roll in flour or rye nuts, and fry in hot fat. Serve with apple sauce or tomato puree.

HAM HASH.

Take equal parts of mashed potatoes and finely chopped boiled ham. Mix with several well beaten eggs and fry in the form of a large flat cake. Serve with macaroni.

MEAT CAKE.

Soak some stale bread in cold water. Press out very dry and mix fine. Add some finely chopped onions, parsley, and a little pepper, and mix with one-third or one-half of finely chopped left-over or fresh meat. Mix all well and shape into a loaf. Bake in an oven with moderate heat. Add boiling water and fat. Baste occasionally, and bake one hour. When done, thicken the gravy with a little flour. Serve for dinner with salad of greens.

SMALL MEAT CAKES.

Prepare the same as the foregoing. Shape into small balls and fry in hot fat.

TURKEY.

Wash and clean the turkey, stuff it with tart apples, cut into quarters, to which a half cup of dried currants and half cup of bread-crumbs or rye nuts have been added. Sew it up, flavor and cover with sliced salt-pork or bacon. Fill the pan one-third full of boiling water, add onions, cover and roast from two to three hours. Add more water, if necessary. Serve with cranberry sauce. Use the gravy left in the pan the next day, with steamed potatoes or rice, for breakfast or dinner.

TURKEY STEW.

Cut off the wings, neck, and legs, before roasting the turkey. Put to boil with a small veal bone, add the giblets and stew until tender. Prepare a butter sauce from the broth. Flavor with onion and parsley.

TURKEY IN GELATINE.

Prepare like turkey stew, and finish like chicken in gelatine.

RIBS OF PORK WITH APPLE FILLING.

Prepare the same as turkey, sew the ribs together and roast two to three hours.

STUFFED TURKEY NECK.

Cut off the neck from a large turkey. Stuff it with a bread dressing to which the giblets, fat and liver of the turkey have been added. Roast it in the same pan with the turkey or prepare it for another meal.

LIGHT BREAD DRESSING FOR TURKEY OR CHICKEN.

Remove the crust from a small loaf of graham bread. Crumble up the soft part and mix with chopped parsley, onion, garlic, thyme, marjoram, sage, salt, one well beaten egg and one-half cup of finely chopped fat of the bird, or suet. This is sufficient for an 8-pound turkey. This dressing is especially good for people with delicate stomachs.

BOILED BACON.

Select firm, eastern bacon. Wash thoroughly with cold and warm water. Let it come to a boil, throw away the water and pour on some fresh water. Boil about an hour. Let it cool on a platter and use the next day. Warm, fat meat is not wholesome for a delicate stomach.

FRIED BACON.

Parboil the bacon for one-half hour. Follow directions for boiled bacon. Let it cool and slice for frying. If the bacon is preferred raw, pour some boiling water over sliced bacon, let stand 5 minutes, pour off the water and fry or broil in the oven.

LEAF LARD.

Chop some leaf lard very fine and let it stand in cold water for several hours, or over night. Fry in an iron skillet, with apples and onions, until crisp and brown. Strain the lard into a bowl and serve the residue warm with stale black bread. Spread the lard on black bread.

BACON FAT.

Remove the fat from boiled or fried bacon and spread on stale black bread. Combine with raw apples. This is good for breakfast.

CHAPTER III.

FISH, CHEESE AND EGGS.

Fish should be cleansed as soon as it is caught, or directly after delivery from the market, and preserved with salt until ready for cooking. If the fish is to be fried, the salt should be washed off, the fish thoroughly dried and rolled in egg and rye nuts, or flour. If the fish is to be boiled, the salt should also be washed off, and the water for seasoning be flavored with spiced herbs. If more salt is necessary, add it to the water.

BOILED FISH.

Prepare as directed in the foregoing.

Fish in gelatine can be prepared with veal bone as directed for chicken. For gravies with boiled fish, see chapter on “Sauces.”

SHELL FISH.

Shell fish, as well as all other fish, should be eaten only when in season. People with chronic constipation and torpid liver should avoid shell fish because they are soft, and easily putrefy. Oysters and clams are a very valuable food for the sick, and also for the

pregnant woman. They are rich in lime substances and nourish the glands of the body. They should be served in combination with lemon and greens, or be prepared with milk.

PICKLED HERRING.

Clean and wash the fish. Place in a colander and add salt. Let stand for several hours. Then, wash the fish and dry; roll in flour and fry in hot fat or oil. Serve warm with lemon, or lay in a stone jar. Add a few bay leaves, whole peppers, and raw onions. Bring some vinegar to a boil with an equal amount of water, pour over the fish and add the fat in which the fish have been fried. If they are kept for several weeks, an extra amount of fat should be added for covering, so as to exclude the air.

FISH CAKES.

Any left-over fish may be made into a nutritious dish for the morning, noon, or evening meal.

Take equal quantities of finely chopped fish and grated potato, beat up several eggs with a little salt and pepper, add some thick cream, and flavor with grated onions. Form into balls with a tablespoon and fry in hot fat. Serve with rice, or with a salad of apples, or tomatoes and lettuce.

CODFISH CAKES.

Take one-third of shredded or finely chopped codfish with two-thirds of grated potatoes; prepare as in the foregoing recipe.

COTTAGE CHEESE.

Put some whole, or skim milk, into a pan and set in a cool room, which has plenty of fresh air. Do not cover the pan. If the room is exposed to dust, put a few long sticks over the pan and cover with a cheese-cloth. When the milk begins to get thick, set the pan into a larger pan with warm water, and keep it in a warm place or in the oven until the curd separates; it must not become hard. Then put a cheese-cloth on a colander and pour the milk into it. Let stand for several hours, until the whey is thoroughly drained off. Then chop fine some green peppers or onions, mix with the cheese, add a little salt and pepper, and serve with apple or potato salad or spread on sandwiches. A few teaspoonsful of sugar and caraway seed may be added in place of the onion and pepper.

SOFT BOILED EGGS.

Put the eggs into cold water, place on the stove, and when the water begins to boil, the eggs will be done.

BOILED EGGS. No. 2.

Pour boiling water over them and let stand on a hot stove for 10 minutes.

BOILED EGGS. No. 3.

Pour boiling water over the eggs and let them stand on a hot stove for 15 to 30 minutes.

SCALLOPED EGGS.

Prepare a plain white sauce, mustard or horse-radish sauce. Cut some hard boiled eggs in halves, pour the sauce over them. Serve with potatoes.

OMELET.

Mix a tablespoonful of flour with a half cup of warm milk or water, and a little salt. Beat up two eggs, mix well with flour and water, then pour into a hot pan in which some butter has been melted. Cover and bake on the stove with moderate heat for eight or ten minutes. Turn if desired. Serve with lettuce and fruit sauce.

SCRAMBLED EGGS.

Beat together one-half cup of soup stock, milk or water, and 3 eggs. Add one-half tablespoonful of flour and mix well. A little chopped, cold, salted meat may be added. Pour all into a hot pan with melted butter, and stir until it is stiff.

CHAPTER IV.

SOUPS.

LEGUME SOUPS.

Soups prepared from legumes, fruits or cereals require an addition of fat in the form of butter, oil, the yolk of an egg, cream, or fat meat.

A soup of peas, beans, corn or lentils may be prepared from left-over food or fresh cooked legumes. To one cup of cooked legumes add three to five cups of hot water or weak soup stock, boil or mix well, then strain. Heat one or two tablespoonsful of butter or half butter and half cooking oil, add to this one or two tablespoonsful of mixed flour, let boil, then add the hot broth at short intervals, stirring to prevent lumps. When all the broth is used, let the whole boil a few minutes. Remove from the fire, flavor with lemon juice, pepper, bay leaves, chopped fresh thyme, sage or parsley, and serve.

To these soups an addition of hot cream may be made before serving, if desired. They form a perfect and an economical meal without the addition of meat, eggs, fish or other protein foods. Celery, lettuce, raw apples and crackers with butter are a good addition. They should be well masticated, and the soup eaten with them very slowly.

BEAN SOUP.

Wash 1½ cup of black, white, red or mixed beans and soak in 1 quart of warm soft water over night. The next day add about 5 pints of cold or boiling water to the beans, let come to a boil; add two finely cut onions and a potato, parsley or other flavoring. Then wash ½ pound of bacon several times with hot and cold water and put on to boil in sufficient water to cover it. Let boil 5 or 10 minutes, pour off the water and put the bacon into the bean soup. Let all boil for about an hour; when the meat is tender, take it out and put on a plate to cool. Let the soup simmer slowly for 3 hours or longer; then strain. Let stand a little while, remove the fat and mix it with 2 or 3 tablespoonsful of flour in a clean saucepan over the fire, add the strained bean soup gradually, let all boil a few minutes and serve. If the soup is desired thin, use only a part of the fat and a little flour. A cupful of strained tomato juice and chopped parsley may be added before serving. This should make five soup plates full. Serve with fried bread or bread and butter and raw carrots.

CREAM OF BEAN SOUP.

Prepare like the foregoing. Leave out the meat, butter, flour, and tomatoes; mix with one-fifth part or less of hot cream before serving. Add plenty of chopped parsley.

PEA SOUP AND CREAM OF PEA SOUP.

Prepare like bean soup. Flavor with celery roots or stems.

TOMATO SOUP.

Strain a can of tomatoes and heat. Add an equal amount of boiling water or soup stock. Heat some oil, butter or fat; add flour, boil a few seconds; then add the tomato juice gradually and a little salt. Boil all 3 to 5 minutes, then serve. It must be of the consistency of gravy. Raw cucumbers and celery are a good addition.

CREAM OF TOMATO SOUP.

Prepare like the foregoing. Add ½ part or more of hot cream before serving. If milk is used, it must be more in proportion than cream.

CREAM OF TOMATO SOUP. No. 2.

Mix 1 quart of hot water or veal stock with 1 quart of strained hot tomato juice. Dissolve 2 to 3 tablespoons of cornstarch in cold water and stir into the boiling fruit juice. Boil 10 minutes, and season with salt and a little sugar, if desired. Remove from the fire, add hot cream, mix and serve. Good in the summer.

HUCKLEBERRY SOUP.

Wash one quart of huckleberries and boil with two quarts of water and a piece of cinnamon. When done strain or leave the berries in the soup. Shape some dumplings with a dessert spoon and boil in the fruit soup until they rise to the top. Use recipe for flour dumplings No. 1. Cherry soup from fresh cherries may be prepared with dumplings instead of thickening.

BLACKBERRY SOUP.

Prepare the same as the foregoing or see recipe for blackberry gruel.

CHERRY SOUP.

Remove the stones from one quart of cherries, and bring two quarts of water to a boil with a stick of cinnamon, pour in the cherries and let them simmer for 20 or 30 minutes. Add enough sugar to counteract the tart taste and thicken with a little cornstarch. Cool and serve with zwieback. If used for supper on hot days it should be prepared in the morning, and allowed to cool. Beaten whites of eggs with a little sugar may be placed on top. Serve on soup-plates.

DRIED CHERRY SOUP.

Soak some dried cherries for several hours. Cook with the desired amount of water and a little sugar and cinnamon. Finish as the foregoing. This is excellent for convalescents during the winter.

PLUM SOUP.

Wash one pound of blue plums and boil with three to four pints of water, a stick of cinnamon and sugar until well done. Thicken with cornstarch, or with sago which has been soaked. Cook 15 to 20 minutes or longer. Run through a colander and add a piece of butter. Cool and serve with zwieback and beaten whites of eggs, if desired. Hot cream may be added in place of butter.

BEEF SOUP. No. 1.

Select a rump piece, wash thoroughly, put into boiling water, add some salt, and skim. Chop fine some green onions, celery, asparagus, parsley, carrots, turnips, add to the soup; young peas, bay leaves, whole pepper and chopped bacon may be added. Cover tightly, and boil slowly for two or three hours. Then brown several tablespoonsful of flour in the same amount of butter, add to the soup, and boil ten minutes longer. Strain and serve. A glass of Madeira or white wine may be added.

BEEF SOUP. No. 2.

Prepare like number one. Instead of brown flour, add one-half cup of barley which has been soaked and boiled in a small amount of water for an hour. Then add to the soup, boil all together for an hour or longer, strain and serve. A good addition to boiled beef is a salad of celery root, or apples, or potato dumplings.

CLEAR SOUP, WITH RICE.

Select some fresh chicken, beef, lamb or several kinds of meat. Wash thoroughly, and put into boiling water, add salt and skim. Flavor with potatoes, onions, or any kind of greens which is most desirable. Boil two or three hours and strain. Boil some rice with salt water in a separate saucepan, bake in the oven until well done. Remove from the fire, add a piece of butter, the yolk of an egg and some grated nutmeg. Stir all well, pour into a dish, serve with the soup like mush and milk.

Clear broth beaten up with yolks of several eggs may be served in cups.

VEGETABLE SOUP, WITH MEAT.

Wash a piece of bacon or ham thoroughly, cover with cold water and bring to a boil. Pour the water off and put on again in boiling water. When the meat is half done add some bay leaves, carrots, celery, young peas, asparagus, parsley, cauliflower, and dried prunes or pears and cinnamon. When the vegetables are tender, brown some butter and flour, mix with finely chopped marjoram and thyme; add to the soup, boil a few minutes longer, and serve. This is excellent in the spring-time. For people with digestive troubles, the soup must be strained. A few raw yolks of eggs may be beaten up with the soup before serving, if desired.

SOUP STOCK.

Wash some beef, mutton or veal bone thoroughly. Put to boil in cold water, skim and cook for four hours or longer. When done, strain into several stone jars or bowls. Let cool and set on ice. When preparing soup, cook the desired amount of vegetables in a little salt water; when tender, add the soup stock, bring all to a boil and strain. This stock can also be used for the preparation of vegetables and purees, especially for people who do not eat meat. Add one-half to one whole cup of stock to the vegetable water and prepare with a butter sauce.

KIDNEY SOUP WITH RICE.

Use soup stock or prepare a clear strong meat soup from middle rib or soup bone to which one or two kidneys have been added. For flavoring tie the tops of celery roots and green onions into a bunch and cook in the soup. The celery and onions can be eaten as a vegetable if desired. Serve with plain water rice as directed for clear soup.

PIGEON SOUP.

Take old pigeon for soup. Flavor with asparagus or young peas. Boil some rice in a little water and salt separately; when half done, add it to the (pigeon) soup and cook an hour longer. Raw yolks of eggs may be added to the soup before serving.

POTATO SOUP. No. 1.

Boil potatoes with salt water and an onion; pour off water, mash potatoes fine, and add the potato water. Bring to a boil some fresh cream and milk in a separate saucepan, and add it to the potatoes. Flavor with a little pepper, and chopped parsley.

POTATO SOUP. No. 2.

Boil the potatoes in plenty of water with salt and onions; drain off water, mash potatoes, and return to the potato water. Then melt some butter, thicken with flour, add the hot potato soup to it gradually, and boil all a few minutes. Bring some fresh milk and cream to a boil, add it to the soup, and flavor with chopped parsley and pepper.

CLAM CHOWDER.

Prepare like potato soup number two, and add clams and hot cream.

OATMEAL SOUP, WITH HAM.

Wash one-half a cup of steel cut oats with cold water. Bring to a boil with two or three quarts of water; add salt, celery, parsley, onions, and about six potatoes. Wash a piece of bacon or ham with plenty of fat on it, parboil it in water for ten minutes, then put it into the soup; boil all for about two hours. Mash and strain. Take off the grease, mix with flour, add the strained soup to it gradually, let boil a few minutes. It can be prepared without meat. This is an economical and nutritious dish.

BARLEY SOUP.

Prepare the same as oat meal soup. Fat meat may be used in place of ham.

KNORR'S PEA SOUP.

Knorr's pea soup can be bought in all first class grocery stores. Time for preparation, twenty minutes. It may be improved by adding hot cream or gelatine to it, or by thickening it with butter and flour. Bean, lentil, green corn, tomato, and several other soup extracts of Knorr's can be prepared in the same manner and improved in many ways if desired. They are very nutritious and save time and labor.

BEER SOUP. No. 1.

Wash and chop fine some dried currants and raisins, put them to boil with one pint of white, stale bread, three pints or more of cold water, a piece of cinnamon, a little salt, a few spoonsful of sugar and about a pint bottle of imported root beer. Boil very slowly for one-half hour or longer, run through a colander. Add some hot cream or a piece of butter and two yolks of eggs.

BEER SOUP. No. 2.

Bring to a boil a pint of imported root beer and a pint of water. Flavor with a piece of cinnamon. Mix two or three tablespoonsful of white flour with cold water, and put into the boiling beer, add some sugar and salt. Boil eight to ten minutes. Remove from the fire, add to it a cupful of hot cream while stirring. Serve with zwieback.

BEER SOUP. No. 3.

Prepare like beer soup number one, in place of white bread use stale black bread or one-half of each. This is excellent for constipation.

MILK SOUPS.

Milk soups may be prepared with rice, buckwheat, barley, tapioca, oats, wheat, flour, corn, macaroni or rye. Oats and barley should be soaked. Rich milk with one-half water is preferable to skim milk or poor milk. Bring the desired amount of milk and water to a boil, stir the grains into it, and boil one-half to one hour. Whole vanilla, cinnamon, or lemon rind may be boiled with it. Salt should not be added until done. It may be flavored with grated bitter almond, fine pepper, mace or nutmeg, or extract of vanilla or other flavoring. Concentrated flavorings should not be added until it is removed from the fire. Yolks of eggs may be added before serving. (Oats, barley and buckwheat do not mix well with eggs.) Sugar is not necessary for milk soups, but if it is desired, it should be added while boiling.

BUTTERMILK SOUP.

Mix some white flour with cold buttermilk, stir over the fire until it boils, add sugar and boil ten minutes. Add hot cream or yolks of eggs or flavoring before serving, as desired.

MILK SOUP WITH MACARONI.

Break some macaroni into boiling salted water, boil fast for 45 minutes. When done, add an equal part of buttermilk or sweet milk. Thicken with a little rice flour.

MILK SOUP WITH FLOUR DUMPLINGS.

Prepare some flour dumplings with or without eggs. Drop into boiling salted water when done, add some hot milk or buttermilk. Thicken with a little flour, add salt and serve. Sweet dried fruits can be added.

BUTTERMILK SOUP WITH RICE.

Cook some rice with water as directed for “Water Rice”; when done add one quart of buttermilk to one quart of cooked rice, mix well and stir over the fire until it boils. Add one-third cup of sugar and simmer with a piece of cinnamon or vanilla for half an hour longer. Add more salt if necessary. Some dried soaked cold prunes, currants or raisins may be mixed with the soup before serving. This forms a perfect meal for dinner on hot summer days or for supper in winter or summer.

ASPARAGUS SOUP. No. 1.

Cut off one-third of the upper end of the asparagus, then wash, cut in pieces and put to boil in water, add some salt; when tender thicken with mixed flour, let boil 10 minutes. Add one-third rich hot milk, flavor with pepper. Serve.

ASPARAGUS SOUP. No. 2.

Prepare as No. 1; when tender, heat some butter, thicken with mixed flour, add the asparagus water gradually and boil a few minutes. Then remove from the fire, stir several yolks of eggs with a little cold water on a soup plate, add the asparagus soup gradually. Flavor with lemon and serve.

BARLEY SOUP. No. 1.

Soak a cup of pearl barley. Boil with two quarts of water, some celery, onions, and finely cut carrots; cook for two hours or longer. Mash all through a colander, add more boiling water if necessary. It must be thick like gravy. Add a piece of butter or a little cream, and serve.

BARLEY SOUP. No. 2.

Prepare like the foregoing, add more hot water when straining. Melt some butter or fat, add one or two tablespoonsful of mixed flour, and part of the barley soup, and cook. When done, mix with the balance of the barley soup. Let all boil up for a few minutes and serve. Add plenty of chopped parsley.

BARLEY SOUP. No. 3.

Prepare like number one or two, boil without vegetables. Leave the barley in it or strain. Mix with cold stewed prunes before serving. Add cream, if desired.

CARROT SOUP.

Scrape and wash some young carrots. Cut into small pieces and stew in water with a little salt. When done, mash up fine and run through a colander. Prepare with butter, flour and soup stock. Add plenty of chopped parsley, also raw pea juice, if desired.

SPINACH SOUP.

Prepare from spinach water, with butter and flour. When done, add a few tablespoonsful of finely chopped spinach. Flavor with grated onion and lemon.

MIXED VEGETABLE SOUP.

Chop up some celery, onion, potatoes, and parsley stems. Simmer in water slowly for 30 minutes. Strain, and prepare with butter and flour. Add plenty of chopped parsley. Finely cut cauliflower, string beans, and peas can be prepared in the same manner. For people with delicate stomachs the pulp of the vegetables should never be pressed through.

BREAD SOUP. No. 1.

Soak some stale white and black bread in boiling water for half an hour. Put on to boil with more water. Cut up a few apples with the skin and add a stick of cinnamon, a little sugar, salt, and some lemon rind. Simmer for 30 minutes or longer. Press through a colander and add some cold soaked raisins or currants and a piece of butter, also the yolk of an egg, if desired.

BREAD SOUP. No. 2.

Prepare like the foregoing. Leave out the apples. Add hot cream or milk in place of butter and egg. Use dried soaked currants or prunes, if desired.

BREAD SOUP. No. 3.

Prepare as the foregoing. Add imported root beer, omit the apples, and use more sugar. Strain and add hot cream or the yolk of an egg and butter. Good for constipation.

BRAN SOUP. No. 1.

Use equal parts of stale bread and bran. Prepare like the foregoing. Leave out the egg.

BRAN SOUP. No. 2.

Prepare like the foregoing. Use more water, and strain. Melt some butter, thicken with mixed flour, add the hot broth gradually. When done, remove from the fire and mix with soaked cold raisins and a few drops of lemon.

BRAN SOUP. No. 3.

Use one cup of bran, four cups of water, four tablespoons of milk sugar. Strain and thicken with butter and flour as directed for Bran Soup No. 2. Omit the fruit. A little lemon may be used if desired. Good for invalids.

CHAPTER V.

CEREALS, NOODLES AND DUMPLINGS.

BUCKWHEAT GROATS.

Wash one cup of buckwheat groats several times with cold water, add about six cups of boiling water and two teaspoonsful of salt. Boil rapidly for 20 minutes or until it thickens, then allow it to cook 50 or 60 minutes longer on the stove or in the oven. Serve with hot cream. Cooked or stewed dried prunes may be eaten with it, or added to the mush just before serving. Buckwheat is a winter food. People who suffer from eruptions on the skin after eating buckwheat should let it alone.

STEEL CUT OATS.

Prepare the same as buckwheat groats. Rolled oats may be used instead.

ROLLED OATS WITH CRANBERRY SAUCE.

Boil two cups of rolled oats with a quart of water and a teaspoon of salt for 20 minutes. Cover and set in the oven, or cook on the stove for about 40 minutes. Remove from the fire, add a piece of butter and a few drops of lemon juice. Serve on soup plates, pour over it cranberry sauce, prune or apricot jam. Eat cold boiled bacon with it, or raw celery or nuts at the end of the meal. It is good for dinner or breakfast.

RYLAX WITH PRUNE JAM.

Prepare like the foregoing. Omit the lemon. Serve with prune jam and fat meat, or with celery or nuts, or with hot cream.

ROLLED WHEAT.

Prepare and serve like rolled oats. Cranberries, prunes, apricots, or apple sauce, are all good additions. The yolk of an egg may be added to the wheat when mixing it with butter.

BRAN MUSH.

Bring one and one-half to two cups of water to a boil, add one-half teaspoon salt. Drop in one shredded wheat biscuit and one-half cup of bran. Mix all well and boil one minute. Serve with hot cream.

BRAN AND RYE MUSH.

Put one-half cup of rylax into boiling, salt water, and cook 20 minutes. When done, moisten one-half cup of bran with a little hot water, and mix with the rye mush. Serve with hot cream.

RAW WHOLE WHEAT.

Soak one-half cup of whole wheat in three-quarters or one cup of warm water over night. Keep the water warm, if possible. A small amount of salt may be added. Serve with cream and dates, or with bananas, carrots, or nuts.

BOILED WHOLE WHEAT.

Soak some whole wheat over night. Boil for several hours with sufficient water and salt. Serve like the foregoing.

POLENTA (ITALIAN DISH).

Stir some yellow corn meal into boiling, salted water in an iron pot. Boil for about 40 minutes and stir well to prevent burning. Eat with a fork, and serve with cheese for breakfast or dinner.

RICE FLOUR. No. 1.

Mix a cup of rice flour with cold water, then add three or four cups of boiling water while stirring. Boil 15 to 20 minutes. Before removing from the fire, add some dried currants, which have been soaked for a while. Put on a soup plate, and pour over it some hot cream.

RICE FLOUR. No. 2.

Use pure rice flour, or one-half cornstarch and one-half rice flour. Prepare as number one. Before serving, mix with a piece of butter and the yolk of one or several eggs, and flavor with vanilla, lemon or bitter almonds. Put on a soup plate, and pour over it hot cream.

CORN MEAL MUSH.

Stir one and one-half cups of corn meal into four cups of boiling salted water; cook 30 minutes; finish like foregoing. Use lemon for flavoring.

BARLEY.

Soak a cup of pearl barley over night in soft water, and the next day boil it in five or six cups of water for two hours or longer. Flavor with onion, if desired, and if it does not become thick enough, dissolve a little rice flour with cold water, and add it to the barley ten minutes before removing from the fire. Serve with cream or with fresh beef, or salted meat and lettuce for breakfast or dinner.

BREAD AND MILK.

Bring some fresh, whole or skimmed milk to a boil, pour on dried black bread or crusts, and add a little salt. Let it stand for 10 minutes and serve on soup plates.

CRACKER AND MILK.

Prepare like the foregoing, or pour one cupful of boiling salted water over one large unleavened cracker, let stand 5 minutes. Then add one cupful of hot milk and serve.

DIRECTIONS FOR BOILING RICE.

Wash one cup of rice, and pour into seven or eight cups of boiling, salted water. Boil rapidly until the grains burst; then cover and put into a hot oven or on a platter, and cook for 20 or 30 minutes. Remove from the fire and add a piece of butter and the yolk of an egg, or serve the rice with hot cream. Dried currants, raisins, apricots or prunes may be mixed with the rice. If eaten in place of mush, pour the rice on soup plates, and add hot cream.

MILK RICE.

Allow a pint of water and a pint of fresh milk to come to a boil with vanilla or cinnamon, and put into it three or four tablespoonsful of Japan or Carolina rice, which has been soaked for several hours. Boil rapidly until the starch granules burst, then boil slowly for forty minutes longer. If it is not thick enough, mix a little cornstarch in cold water, and add to the rice when nearly done. The yolk of one or more eggs may be added before serving, if desired. It may be eaten plain in the form of a thick gruel or with a fruit sauce. It will serve as a whole meal for children, morning, noon, or evening. A few nuts, or some celery, may be eaten at the end of the meal.

RICE CREAM.

Cook one cup of rice like plain, water rice with a stick of cinnamon or vanilla. When done, add the yolks of several eggs and a piece of butter, or some hot cream and two tablespoonsful of sugar, or one-half cup of soaked currants or raisins. Stir over the fire until it boils again. Serve hot or cold with fruit sauce.

ALMOND RICE.

Cook rice with water as directed for boiling rice. When done, remove from the fire, and mix with it some almond butter stirred smooth with a little water. Some dried currants or apricots previously soaked may be mixed with the rice. In combination with a dish of lettuce it will serve as a whole meal. A few whole almonds may be eaten at the end of this meal.

APPLE RICE.

Boil rapidly for 30 minutes one-half cupful of rice with three cupsful of water and a little salt. Peel three medium sized apples, cut them into small pieces after removing the cores, and add to the rice with one tablespoonful of sugar. Cook on the stove or in the

oven until the apples are tender. Remove from the fire, add a piece of butter, and serve with preserved or fresh meat, eggs, fish or cheese. A stick of cinnamon may be boiled with the rice for flavoring.

APRICOT RICE.

Prepare as apple rice, and let the rice boil until tender. Then drain a few preserved or canned apricots and add them to the rice, also a piece of butter or one-half cup of hot cream. Mix well. Serve with lean meat, eggs, or cheese.

CHERRY RICE.

Prepare like apple rice, and use ripe black cherries, or canned cherries. Omit the juice. A tablespoonful of sugar may be added to the fruit while boiling. It is necessary to have the rice boiled in sufficient water, and long enough to allow each grain to burst before the fruit is added, or the acid of the fruit will prevent the rice from softening. Butter alone, or butter and the yolk of an egg, should be added when acid or sub-acid fruits are mixed with cereals. Serve with sterilized cream or with eggs, or eat nuts at the end of the meal.

CURRANT RICE.

Prepare like cherry rice. Add fresh ripe or dried currants in place of cherries. Serve with sterilized cream or with fried or boiled eggs, or with bacon.

RHUBARB RICE.

Prepare like the foregoing. Use sterilized rhubarb which has been cooled. Serve with sterilized cream.

TOMATO RICE.

Prepare like apple rice. Use one-half to one cupful of strained, canned tomato juice. Omit sugar. An onion may be boiled with the rice, if desired. Serve with fried eggs or fish, and greens.

BROWN RICE.

Brown the rice in butter to a light yellow color. Add sufficient boiling water and salt, and boil one-half hour or longer. Dried mushrooms may be added, if desired. Serve with meat, fish, or eggs.

CARROT RICE.

Put some rice to boil in water with salt. Cut young French carrots into small pieces and add; both will be done about the same time. Add finely chopped parsley and a piece of butter. Serve with peas puree and fat meat, or with fish.

MACARONI WITH CREAM.

Break up some macaroni and put in a saucepan, adding boiling water and a little salt. Boil for 30 minutes, and add more water if necessary. Dissolve some rice flour in a little cold water and thicken the macaroni, then cover and bake in an oven for 30 minutes or longer. Heat some rich cream in another saucepan and mix with the macaroni, and serve. Flavor with a little pepper, or finely chopped, salted, lean meat or parsley.

MACARONI WITH STOCK.

Prepare as the foregoing, boil 30 minutes, then add some stock and a little strained tomato juice. Cover and put in the oven again for 30 minutes. Serve with grated cold cheese.

NOODLES.

Beat two eggs with two large tablespoonsful of water and a little salt. Mix with sufficient white flour to make a stiff paste. Put some flour on a wooden board, knead the dough and add more flour until hard and dry; then roll out as thin as possible, dry in the sun or on a table, and cut into fine strips. Boil in salted water for half an hour. Serve with boiled beef or preserved salt meat, or with grated Swiss cheese and lettuce.

DUMPLINGS.

LIGHT FLOUR DUMPLINGS.

Cream a tablespoonful of butter, and add to it a whole egg and the yolk of one egg, some salt, nutmeg, chopped parsley, and two tablespoonsful of flour. Stir well for several minutes. Form small dumplings with a spoon, put into hot soup and boil eight minutes.

POTATO DUMPLINGS. No. 1.

Cream a tablespoonful of butter, add to it three yolks of eggs, a cup of cold grated potato, and one cup of dry bread crumbs. Flavor with lemon, rind, salt and nutmeg, and mix the beaten whites of two eggs with it. Roll out into small dumplings, and boil eight minutes in soup or water.

POTATO DUMPLINGS. No. 2.

Mix two cups of cold grated potato with two-thirds of a cup of flour and one-half cup of creamed butter, adding the yolks of four eggs, the whites of two eggs, and salt and flavoring. Mix well and form dumplings. Boil in hot water for about 15 minutes. Serve with roasts.

BREAD DUMPLINGS. No. 1.

Put some stale white bread or rolls to soak in cold water and press out as dry as possible. Add a tablespoonful of creamed butter, the yolks of two or three eggs, salt and nutmeg. Add the beaten whites of two eggs. Form dumplings with a spoon and boil in water, soup or fruit juice until they swim on top. Serve with stewed prunes or apricots.

BREAD DUMPLINGS. No. 2.

Remove the crust from one-third of a loaf of milk bread and soak the soft part in cold water for 5 minutes. Put it into a clean cloth and force out the water. Cream three tablespoonsful of butter, or melt some soup fat, mix with the bread and stir it very smooth. Let it cool, and add the yolks of four eggs, salt, a little mace, some finely chopped parsley, and onion, if desired. Then beat the whites of two eggs, mix with the mass and form dumplings with a dessert spoon. Put them into the boiling soup and cook for about 5 minutes or until they swim on top.

BAKED CORN MEAL DUMPLINGS.

Boil in two cups of milk or water two cups of white corn meal with a tablespoonful of butter, stirring all the time, until the mass is very thick. Let cool. Flavor with lemon rind and nutmeg, and mix with three or four well beaten eggs. Shape into dumplings with a spoon, turn in rye nuts or bread crumbs, and bake in butter. Serve with sugar and cinnamon, or with apricot, apple or wine sauce.

MIXED DUMPLINGS.

Mix over the fire one and one-half cupsful of flour with two cupsful of milk and a large tablespoonful of butter, until it does not stick to the saucepan. Let it cool, add the yolks of four eggs, salt, cinnamon, a tablespoonful of sugar, one-half cupful of finely cut fried bread crust and bacon, then the beaten whites of eggs. Form medium sized dumplings with a tablespoon, and boil in salted water for 5 or 6 minutes. Serve with stewed pears, cranberries or prunes. They are also good with sauerkraut.

FLOUR DUMPLINGS. No. 1.

Mix one cupful of flour with one-half cupful of melted butter, one cupful of hot water, and some salt. Stir well on a hot stove until no more lumps appear. Cool a little, then mix with several yolks of eggs, and flavor with mace, chopped parsley or other spices. Dip a spoon in hot water and form dumplings of the desired size. Put into boiling salt water or on top of stewed fruit, and boil 6 or 10 minutes, or until they rise. The spoon must be dipped into hot water each time before forming a dumpling. Serve with peas or stewed fruit.

FLOUR DUMPLINGS. No. 2.

Mix one cup of white corn meal and one cup of flour with a little cold water, and stir it into boiling milk. Let it soak for 5 minutes or until it is thick. Then add a piece of butter, salt, and flavoring; let cool, mix with several yolks of eggs, and shape dumplings with a spoon, and put into boiling soup or blackberry juice. Boil about 10 minutes, or until they swim on top.

FLOUR DUMPLINGS. No. 3.

Mix some white flour, or three-fourths white and one-fourth rice flour, with baking powder and salt. Shorten with butter and fat like dough for pie. Roll out, enclose some apples and bake in the oven for 20 minutes or longer.

FLOUR DUMPLINGS. No. 4.

Mix some flour with baking powder and salt. Stir to a light paste with cold water, adding several eggs or yolks of eggs. Boil with meat stew or in water.

CHAPTER VI.

BREADS, CAKES AND PUDDINGS.

POMPERNICKLE OR BLACK BREAD.

Prepare a sponge with a pint of white flour, three-fourths of a yeast cake, a little salt and sugar, and a pint of warm water. When light, add two quarts of rye meal, a tablespoonful of salt and about one quart of water. Mix well, and let rise over night. The next morning add about one quart of warm rye meal, and one of white flour; knead the dough for at least one-half hour. Let rise again, knead a little more, and shape into loaves. When light, bake in a hot oven, for about an hour. Pure rye meal may be used in place of one-fourth white flour.

WHOLE WHEAT BREAD.

Prepare the same as black bread. Use whole wheat flour in place of rye meal.

LIGHT WHOLE WHEAT BREAD.

Make a sponge from one cupful of luke warm water and one cake of yeast, with enough white flour to make the thickness of sponge cake. Cover and set in a warm place, about 90 degrees F. When foamy, add about three pints of luke warm water, or milk which has been scalded and cooled to luke warm, about two teaspoonsful of salt, a little sugar and a piece of butter or fat. Stir into it with a spoon sufficient white flour to make it of the same consistency as the first sponge. Beat it from 10 to 15 minutes, dust the top with flour, and put it into a warm place to rise. When light, add enough whole wheat flour to make a stiff dough. Put it on bread-board with flour to prevent sticking, knead for half an hour or longer, and let it rise again. When light, shape in loaves without kneading, put into pans and prick top with a fork several times. When sufficiently raised, bake in hot oven for about an hour. Cover top with pieces of oiled paper, the first 20 or 30 minutes. When done, put the bread on a sieve or in towels to cool.

LIGHT GRAHAM BREAD.

Prepare in the same manner as light whole wheat bread.

WHITE BREAD.

Prepare the same as whole wheat bread, using pure, rich milk, cream and water, or sweet whey. Add a large piece of butter or cocoanut. Use white flour instead of whole wheat, mix it with one-fourth white corn meal, or rice flour.

COFFEE CAKE.

Prepare the same as white bread, using less flour, and add a few well beaten eggs, the grated rind of several lemons and oranges, or flavor with nutmeg, dried fruit, vanilla, mace or bitter almonds. Serve with fresh, sweet milk, or with scalded milk, as a whole meal for supper.

All breads and cakes made with yeast are more nutritious and wholesome when stale, on account of the evaporation of water and the changes which take place in the bread. They should be kept in tins with holes on all sides, to allow a perfect circulation of air.

The tins should be placed in the sunlight, or on a high, dry place near a stove. In many foreign countries pompernickle is kept for many months during the winter by placing it on top of high stone ovens near the ceiling. It finally assumes a sweet taste similar to that of nuts.

Bread and cake may be kept sweet and free from mildew for a long time in the following way: Cut it with a sharp knife, when about four days old, into slices about one inch thick, then place it on a large, wire screen in the hot sunshine, cover with a cheese cloth, and let it lie for several hours, turning each slice until thoroughly dry. Then place the slices in an upright position in a square box made of wire screening, and keep in a dry or sunny place, covered with a light cloth. The box may be placed in the sunshine several times a week.

ROMAN MEAL BREAD.

Prepare the same as whole wheat bread, and use Roman meal instead of whole wheat flour.

BISCUITS.

Mix one quart of white flour with one-fourth of entire wheat flour, corn meal, or rice flour. Mix it thoroughly with two level teaspoonsful of salt, and four of baking powder. Rub into it two tablespoonsful of vegetable fat or butter. Mix with rich milk and prepare as usual. Serve with salted, preserved meat and eggs, or with rich cheese and olives and salad of greens.

POP-OVERS.

Grease the iron gem pans, and place on the stove or in the oven, to have them very hot. Then beat two eggs very light, mix a cup of rich milk with a cup of flour, and a half teaspoonful of salt; add the eggs and beat with an egg beater until all is very light. Pour the mixture into the pans, filling two-thirds full, and bake in a quick oven. This will make about eight pop-overs.

BRAN MUFFINS.

Mix one cupful of white flour with one-half cup of graham flour and one and one-half cups of finely sifted bran. Rub into it three tablespoonsful of butter; then add one and one-half cups of sour milk, a teaspoonful of soda, a little salt and three tablespoonsful of molasses. Put into hot muffin tins, and bake in a hot oven.

BRAN BREAD.

Beat the whites of three eggs to a stiff snow, add a little salt, and mix with two tablespoonsful of fine, sifted bran, and two of fine rye nuts. Put the mixture on a pie tin and bake in a very moderate oven. Leave the door open. Serve with apple salad and lettuce.

BOSTON BROWN BREAD.

Mix together one cup of coarse corn meal, one of rye flour, one of graham flour, and a teaspoonful of salt. Dissolve two teaspoonsful of soda in two cupsful of sour milk and mix with the flour, adding three-fourths cup of molasses. Pour into narrow, oiled tins, and steam for four hours. Serve with lettuce, celery and apple, or tomato salad, and nut butter.

WHITE MUFFINS.

Use mixed flour, or rice and wheat as suggested for white bread. Mix with baking powder and salt. Use two eggs and about one and one-half cups of rich milk to about three cups of flour. Serve with tomato or peas puree and lettuce for breakfast or supper.

PASTRY FOR TARTS OR PIES.

Mix one and a half cups of white flour with one-half cup of rice flour. Add one-half teaspoonful of salt, shorten the flour with three tablespoonsful of butter and three of oil. Then add to it the yolks of two eggs beaten with sufficient ice cold water and a little rum to make a paste which is not very stiff. Roll it several times, then cover and put it in the ice box for an hour.

SAND TART.

Mix one-half pound of white flour and one-half pound of rice powder, or wheat starch. Keep in a warm place. Melt one pound of butter, cool and cream with one pound of sugar, adding ten yolks of eggs, alternating with the flour. Stir the mass for one-half hour,

add the rind of two lemons, the juice of one-half lemon, and two tablespoonsful of rum. Beat the whites of ten eggs, mix lightly with the dough, and add a teaspoonful of baking powder. Bake in a moderate oven for one and one-half to two hours. During the first half hour have more heat at the bottom than at the top. During the last half hour have little or no heat at the bottom. The cake tin should not be moved.

The tart may be baked in layers or on round tins and be mixed with different colors, if desired.

PLAIN CAKE.

Cream one-half cup of butter with one-half cup of sugar, add two eggs, two cups of flour, two teaspoonsful of baking powder, a little salt, one cup of water, one-half cup of raisins or currants, and any kind of flavoring. Bake in cake tins. Cake prepared with water is more wholesome than with milk.

FROSTING.

Cream equal quantities of butter and chocolate. Spread on the layers when cold. Frosting prepared from pure sugar is unwholesome.

STRAWBERRY SHORT CAKE.

Prepare a light biscuit dough, bake in tins and cover with strawberries and whipped cream. Use no more sugar than is necessary.

FRUIT CAKE.

Chop up one cup of currants, citron, and raisins, and mix with one cup of flour. Sift one cup of flour with a teaspoonful of soda, one of cinnamon, and a little salt. Cream one-half cup of butter with one cup of brown sugar, one-half cup of molasses and two well beaten eggs; add the flour, fruit and one-half to three-fourths cup of strong black coffee. Stir well and bake in a moderate oven for one hour.

MIXED FLOUR.

Mix two cups of white flour with one cup of rice flour and one of cornstarch. Sift and keep in a tin box for sauces and soups.

RYE NUTS. No. 1.

Remove the outer crust from a loaf of stale pompernickel and grate the soft part on a grater. Pour the crumbs on a large piece of paper, and dry in the sun or in an oven. Keep in a dry place, in a tin with good ventilation.

RYE NUTS. No. 2.

Cut a loaf of stale pompernickel into thin slices and remove the crusts. Cut the inside into small strips, lengthwise and crosswise. Allow it to dry thoroughly in a moderate oven or in the sun, and while still warm, grind it through a coarse meat grinder. Place it again in an oven or in the sun to dry, or brown slightly. If desired as fine as grape nuts, grind it again or sift it, and keep in a dry place. It may be mixed with one-half grape nuts. Use as directed in menus and recipes. The outside crusts may be dried in the oven or sun, and kept in tins. The crusts are an excellent addition to milk soups or other soft foods.

SUN DRIED BREAD.

Cut stale pompernickel, whole wheat or white bread into slices, then cut in strips crosswise and lengthwise to the size of lump sugar. Allow it to dry in a moderate oven or in the sun. Keep in a dry place in sacks or tins. Use with milk as directed in recipes. It may be dried in slices and eaten in place of fresh bread.

FRIED BREAD.

Cut into strips as directed in the foregoing recipe. Fry in hot oil, or butter and oil. Serve with legume or fruit soups.

CRUSTS.

Cut some stale whole wheat or black bread into slices. Remove the outer crusts with a sharp knife and dry them in an oven. Keep in a tin box in a dry place.

IMPERIAL STICKS.

Cut stale buttered bread into long narrow sticks, and brown in the oven.

CORN BREAD. No. 1.

Three-fourths of a cup of white or yellow corn meal, one and one-fourth cups of white flour, one teaspoonful of salt, two tablespoonsful of butter or one-half oil and one-half butter, two teaspoonsful of baking powder, two well beaten eggs, one and one-half cups of rich milk, and sugar, if desired. Bake in a quick oven for 30 minutes.

CORN BREAD. No. 2.

Bring one quart of water to a boil, and add a teaspoonful of salt. Stir about one cup of coarse yellow corn meal into it and let boil 30 or 40 minutes. Then take it off the fire, beat thoroughly with a spoon, and cool until lukewarm. Add a large tablespoonful of oil or butter, a little lemon juice and four yolks of eggs. Stir well, and add the beaten whites of the eggs. Put the mixture into a flat, oiled pan and bake or heat on a griddle. Small cakes may be formed from the batter and baked in an oven or fried until browned nicely. The whites of eggs may be left out, if desired. Serve with salads of lettuce, watercress, tomatoes or apples, or with fruit sauces. Acid and super-acid fruits combine best with this bread.

CORN BREAD. No. 3.

Prepare the same as number two, using white corn meal. Flavor with cinnamon, vanilla or bitter almond, and mix with dried, soaked fruits as currants, finely cut apricots, or prunes, or serve with a fruit sauce prepared from blackberries, huckleberries or the above mentioned fruits.

DOUGHNUTS.

Use four eggs, a small cup of sugar, two cups of rich fresh milk, a teaspoonful of salt, and about one quart of flour finely sifted with two teaspoonsful of baking powder. Add grated lemon rind or cinnamon, for flavoring. Beat the dough until very light. Drop by the tablespoonful into hot fat. Stewed cold prunes or apricots may be placed in the middle of each doughnut. They may be served with fruit soups, fruit sauces, or green salads for dinner in the summer, or for supper in the winter.

CEREAL OMELET.

To two cupsful of left-over boiled wheat add two well beaten eggs, half a teaspoonful of salt, finely chopped parsley and onion. Heat butter and oil in a frying pan, and pour into the mixture. Cook by moderate heat until firm. Serve with crisp bacon, if desired.

HOMINY CAKES.

Prepare the same as Cereal Omelet or mix with eggs only, and serve with fruit sauce.

BREAD OMELET.

Remove the crust of one-half loaf of stale milk bread. Soak the bread in cold milk or water for 5 minutes. Lay it in a cloth and press out as dry as possible. Cream one-half cup of butter with one-half cup of sugar; add one-half cup of dried currants, one-half cup of almond meal, the rind of one or two lemons or oranges, four yolks of eggs, some cinnamon or mace and a little salt. Mix well, and add the beaten whites of four eggs. Heat a large flat pan, oil it well, sprinkle with rye nuts and pour in the batter. Bake on a medium hot stove, turning the omelet, or bake in the oven. Serve with fruit sauce and green salad.

SNOW BALLS.

Place four eggs in warm water. Mix two cups of flour with a cup of warm water, salt, and one-half cup of melted butter. Stir it over the fire until the flour does not stick to the saucepan. Let cool and mix with the eggs. Beat the dough for about ten minutes. Shape balls with two tablespoons, and bake in the oven or fry in hot, deep fat. Sprinkle with sugar and serve for afternoon tea or for

supper.

EGG TOAST.

Soak slices of stale bread in milk, and beat up some eggs with a little salt and cinnamon. Turn the soaked bread into the egg, and fry in hot butter. The milk and eggs may be beaten up together and the bread soaked in it before frying. Serve with apple, cranberry or apricot sauce, or with syrup and lettuce. This is suitable morning, noon or night.

RICE FRITTERS.

Mix some left-over rice with several well beaten eggs, and the grated rind of a lemon. Bake on a hot griddle. Serve with fruit sauce and lettuce, morning, noon or night.

UNLEAVENED GERMAN PANCAKES. No. 1.

Use six eggs, six tablespoonsful of flour, one and one-half cup of warm milk, one-half cup of cream, and a little salt. Mix well the yolks, salt, cream, milk and flour, then add the whites of the eggs beaten stiff. The dough must be of the consistency of thick cream. Bake in thin layers in half butter and half oil, in a small pan. Serve with lettuce and fruit sauce or with French dressing at the noon meal.

GERMAN POTATO PANCAKES. No. 2.

Grate five large raw potatoes and one onion. Mix two tablespoonsful of white flour with a little warm water and a cup of rich cream, add salt and mix with the potatoes. Then add three whole eggs beaten well, and fry in hot fat like griddle cakes, until brown. Serve with apple sauce, or lettuce and French dressing.

GERMAN PANCAKES. No. 3.

Mix one pint of white flour and one-fifth pint of rice flour with one pint of rich warm milk, or with one-half milk and one-half warm water, and a teaspoonful of salt. Beat four whole eggs, add to the mixture and beat with an egg beater for a few minutes, until perfectly smooth. Bake on a small, shallow, iron, griddle, using about four tablespoonsful of the mixture for each cake. The fat used for frying must be boiling hot. Pile on a plate standing over hot steam until all are done. Cut in sections and sprinkle with sugar, if desired. Serve with green salads or apples, or with apple, apricot or cranberry sauce.

PLUM PANCAKES.

Prepare the batter a little thicker than the foregoing. Peel and slice some blue plums very thin, mix with the batter and bake as above.

GERMAN PANCAKES WITH BACON.

Cut some bacon into narrow short strips. Fry until crisp, place in a bowl and mix with a piece of butter or with oil. Keep it in a warm place while baking the pancakes. Pour some fat and six pieces of bacon into the pan for each cake, and bake the same as German pancakes. Do not allow a metallic spoon to remain in hot fat.

APPLE PANCAKES.

Peel some apples and cut in thin slices. Mix with the dough as directed for German pancakes and fry on both sides. If fewer eggs are used, take a little more flour.

CHERRY PANCAKES.

Remove the stones from ripe black cherries. Prepare the dough as directed for German pancakes, mix the cherries with it and fry in hot fat.

BUCKWHEAT CAKES.

Mix prepared or unleavened buckwheat flour with sweet cream or one-half cream and one-half water, and bake on a hot griddle. Serve with fruit sauce or French dressing at the morning or noon meal.

ROMAN MEAL CAKES.

Soak two tablespoonsful of dried currants in a little hot or cold water. Mix one-half cup of flour with one teaspoonful of baking powder, a little salt, and one cup of Roman meal. Beat two eggs very light, with about one-half cup of water, mix with the flour and currants and bake in hot fat. Serve fruit sauce with them.

MATZOON PUDDING.

Soak matzoon in cold water or milk for several minutes. Then press out dry, stir until fine and mix with several well beaten eggs, cream, or butter, and raisins, chopped apples, currants, lemon rind or any other flavoring. Heat a cupful of oil or suet in a high iron pot, put the pudding mixture into it and bake in a moderately hot oven for about one hour. Serve warm with fruit sauce or wine sauce.

MATZOON CAKES.

Prepare the same as the foregoing. Shape into small balls with two tablespoons and fry in hot fat.

FISH PUDDING.

Cream three-fourths of a cup of butter, add to it four eggs, nutmeg, salt, parsley, two cups of bread crumbs, four cups of finely chopped left-over codfish or salmon, and some lemon juice. Mix well and steam one and one-quarter or one and one-half hours. Serve with a butter sauce prepared with soup stock.

MEAT PUDDING.

Prepare like fish pudding. Use four cups of finely ground meat in place of fish.

LIVER PUDDING.

Prepare like fish pudding. Use three and one-half cups of grated or ground left-over liver and one-half cup of finely chopped cold, fat meat or suet. Serve with caper or tomato sauce.

POTATO PUDDING.

Cream one-half cup of butter with one-half cup of sugar, add the yolks of six eggs, two cups of grated potatoes, salt, cinnamon and the rind of one lemon; then add one cup of black or white bread crumbs and the beaten whites of six eggs. A half cup of almond meal mixed with a few bitter almonds may be added to the mixture, if desired. Bake this pudding for about sixty or seventy minutes, or boil two hours. Serve with stewed prunes or apple sauce.

PLAIN BREAD PUDDING.

Soak some stale bread in cold water, press it out thoroughly and stir smooth over the fire, with some butter or fat. When cool, add salt and several well beaten eggs or some flour, syrup and chopped suet, mix well and add any desired flavoring or sugar. Tie in a cloth and boil for two hours in salt water, or with white beans. Serve with stewed fruit.

RICE PUDDING.

Cook some rice as directed for water or milk rice. When cool, cream some butter with an equal amount of sugar, and add several well beaten eggs, lemon rind, cinnamon, a little bread crumbs, some raisins or currants and some sweet or sour cream, or melted butter. Bake for about an hour.

SAGO PUDDING.

Soak the sago and cook with one-half water and one-half milk. Finish like rice pudding.

FLOUR BREAD PUDDING.

Mix over the fire two cups of flour with two cups of milk or water, and three-fourths of a cup of melted butter, until the batter loosens from the bottom of the saucepan. Let it cool a little and add the yolks of four eggs, two tablespoonsful of sugar, two cups of bread crumbs, salt and mace. Then beat the whites of four eggs, mix and add one-half glass of cognac. Pour the mixture into an oiled pudding pan and steam two and one-half hours. Serve with stewed plums, pears, or cherries.

CORN MEAL PUDDING.

Bring two cups of milk to a boil, and mix four cups of yellow or white corn meal with a pint of cold water. Stir into the boiling milk and add two tablespoonsful of butter. When it is thick, remove from the fire and cool. Cream half a cup of butter with three-fourths cup of sugar, add the yolks of four or five eggs, salt, lemon rind, several grated bitter almonds, and the beaten whites of the eggs. Put into a pudding pan and steam from two to two and one-half hours. In place of bitter almonds use lemon juice, if desired. Serve with white or red wine sauce, or with stewed apricots or cranberries.

RICE FLOUR PUDDING.

Prepare the same as corn meal pudding.

APPLE-BREAD PUDDING.

Grease a pudding dish and fill with alternate layers of mixed bread crumbs and apple sauce. Begin with bread crumbs, using whole wheat or rye nuts. Mix the apple sauce with a large piece of butter, while still warm. When the dish is filled, beat up two eggs with a tablespoonful of sugar, one-half cup of cream, a little salt and some cinnamon; pour it over the top and bake in moderate hot oven for forty or fifty minutes. It affords a perfect meal for the evening. If served at noon, eat some nuts at the end of the meal.

BAKED BREAD PUDDING.

Pour two pints of hot milk over two cups of bread crumbs, cool a little, then cream one-half cup of butter with one-half cup of sugar, mix with the bread crumbs, adding three well beaten eggs, a teaspoonful of salt, a little nutmeg or cinnamon, the juice of one-half a lemon and the rind of two lemons. Mix well together, and bake in a buttered dish for fifty or sixty minutes. Serve with wine sauce, lemon, cherry or any kind of fruit sauce. Dried fruits may be mixed with the batter. Serve for supper, using broth, meat soup, or cream soup at the beginning of the meal. Celery is an excellent addition to almost any food at the evening meal.

VEGETABLE PUDDING. No. 1.

Prepare as baked bread pudding. Use legume soup in place of milk, leaving out the sugar. Use butter or cream and mix with two tablespoonsful of peanut butter or other nut butter or walnut meats. The eggs can be omitted. Flavor with finely chopped onions, celery and parsley. Pour on oiled pie tins and bake thirty to forty minutes. Serve with tomato sauce or string beans for dinner.

VEGETABLE PUDDING. No. 2.

Boil some rice with salt and water. Add a cupful of thick legume puree and finish like the foregoing.

STEAMED BREAD PUDDING.

Soak some stale bread in cold water, press out dry, and stir smooth. Melt one-third of a cup of fat and one-half of a cup of butter, and mix the bread with it on a hot stove, stirring until it loosens from the saucepan. Cool a little, and flavor with mace, nutmeg, lemon rind or cinnamon and salt. Add several well beaten eggs and some finely cut dried fruit. Mix well and steam from one to one and one-half hours. Serve with lettuce and fruit sauce. In place of fruit and the above flavoring, chopped parsley, onions and pepper, bacon, anchovy, capers or codfish may be used. Serve with tomato or apple sauce.

SUET PUDDING.

Mix four and one-half cups of flour with three cups of milk, one-half pound of finely chopped suet, four well beaten eggs, four tablespoonsful of sugar, a teaspoonful of salt and the rinds of two lemons. Grease a pudding pan, sprinkle some black or white bread crumbs into it, pour in the batter and steam for two hours. Serve with stewed fruit, cherries, pears, or plums, or with wine

sauce, for dinner.

UNCLE TOM'S PUDDING.

Mix one-half a pound of flour with one-half a pound of syrup. Then chop fine one-fourth of a pound of suet, and mix with a little flour. Beat one-half a pint of milk with two eggs, and add a half cup of sugar, salt, mace, cinnamon, cloves and one tablespoonful of soda. Mix well and pour into a pudding dish, and steam for two hours. Serve with wine sauce No. 1 or with fruit sauce.

BLACK BREAD PUDDING.

Cream one cup of butter with three-fourths of a cup of sugar, and add the yolks of five eggs, three-fourths of a cup of dried currants or raisins, the rind of a lemon, a little cinnamon and cloves, salt, three cups of grated black bread and one-half a glass of wine or brandy. Mix well and add the beaten whites of the five eggs. Oil a pudding pan and pour the mixture into it. Steam two and one-half hours, and serve with vanilla, or white wine sauce. A cupful of rich cream, diluted almond butter or one-half cup of almond meal may be mixed with the batter, if desired.

PLUM PUDDING. No. 1.

Moisten two cups of bread crumbs with a little cream, and add two cups of finely chopped suet, two of currants, two of raisins, one of sugar, one-half cup of almond meal, one-half cup of finely chopped orange and lemon rind, a little nutmeg, salt, one-half glass of brandy and two or three well beaten eggs. Mix all well and steam in a cloth or pudding pan for five hours.

PLUM PUDDING. No. 2.

Use two cups of flour, one-half cup of bread crumbs, one cup of rich milk, and a little fruit. Mix and boil like No. 1. The almond meal may be left out.

CHAPTER VII.

SAUCES AND SALAD DRESSINGS.

SAUCES.

Sauces are a necessary addition to cooked foods, especially in cold weather. The proper utensils used for sauce making are wooden spoons and flat, round bottomed saucepans.

Good fresh butter, oil and dry flour are necessary to make nutritious sauces. Flour for thickening should boil at least ten minutes. If the flour is to be cooked with fat before the liquid is added, only a few minutes of boiling is necessary, for the reason that fat, when boiled, reaches a higher temperature than water or milk. Mixed flour is preferable to pure wheat flour. Sauces prepared from soup stock, vegetables or fruits and gelatines are a better addition to meats than brown gravies, which are prepared from the small amount of juice which is extracted from the meat by roasting. Sauces prepared in the latter way are too rich as a food if eaten in combination with meat; they are a perfect meal by themselves if eaten in combination with whole wheat bread and greens.

BUTTER SAUCE. No. 1.

Melt three tablespoonsful of butter, or half butter and half oil, mix with two tablespoonsful of flour over the fire, and boil for a few seconds. Then add gradually a pint of boiling water or soup stock or hot whey, while stirring it. Boil a few minutes. Flavor with salt, onion, chopped parsley, celery, nutmeg, bay leaves, anchovy-paste, lemon, chopped salted meat or whatever flavor is desired. Serve with meat or fish.

BUTTER SAUCE. No. 2.

Prepare like the foregoing. Use milk in place of water, or soup stock.

TOMATO SAUCE.

Prepare as number one, using strained tomato juice instead of water. Serve with meat, fish, or grains.

CAPER SAUCE.

Prepare as number one, add capers and lemon before serving.

HORSE RADISH SAUCE.

Prepare as number one, adding dried currants and grated horse radish at the last minute. This is excellent with boiled beef or fish.

MUSTARD SAUCE.

Prepare as number one, adding two to four teaspoonsful of prepared mustard a minute before serving. Serve with hot or cold boiled beef, or with hard boiled eggs.

MUSHROOM SAUCE.

Prepare as number one, add the desired amount of dried mushrooms, which have been soaked in water for several hours, and boil for ten minutes. Serve with poultry, game or rice.

CREAM SAUCE. No. 1.

Prepare as number one; remove from the fire, add a few tablespoonsful of hot cream, or the yolk of one or several eggs, which have been diluted and stirred with a little cold water. Flavor with mace, pepper, nutmeg, parsley, lemon, or vanilla. Serve with macaroni, boiled fish, plum pudding, French toast, chipped beef, salted meat or boiled onions.

CREAM SAUCE. No. 2.

Thicken some water or soup stock with flour. Cook ten minutes, and add hot cream and flavoring.

ALMOND SAUCE.

Prepare with hot water as directed for butter sauce. Stir smooth a tablespoonful of almond butter or paste with two tablespoonsful of cold water, remove the sauce from the fire, add the almond butter and stir thoroughly. Serve with baked apples, rice, or bread.

OLIVE SAUCE.

Prepare as butter sauce. Soak some olives in warm water, remove the stones and add to the sauce, boiling all a few minutes. Serve with duck, game, fish or meat.

DRIED CURRANT SAUCE.

Soak the currants in boiling water, and let stand thirty minutes. Prepare a plain butter sauce from butter, flour, and hot water, and when done mix the currants with it. It can be prepared with soup stock or fish-water, and served with boiled white fish or boiled beef.

BACON SAUCE.

Cut some bacon into pieces about the size of lump sugar. Fry until brown. Pour the fat into a stone jar and put the bacon on a plate. Mix a tablespoonful of the bacon fat and one of butter with a tablespoonful of flour, and add hot water, whey, or soup stock. Flavor with chopped parsley or strained tomato juice and add the bacon.

FLAVORING OF MEATLESS SOUPS AND SAUCES.

Soups and sauces prepared with flour and water may be improved by an addition of left-over meat gravies or with crisp bacon and flavored with finely cut onions.

MINT SAUCE.

Wash half a handful of young fresh mint, pick the leaves from the stalks, and chop them very fine. Make a plain butter sauce with soup stock, and add vinegar and sugar to suit the taste. Then remove from the fire, mix with the chopped mint, and serve with lamb

or mutton.

LEMON SAUCE.

Wash a lemon, remove the peel and steep in three cups of water for fifteen minutes. Add the juice of one or two lemons and the necessary amount of sugar. Dissolve three teaspoonsful of cornstarch with a little cold water and stir into the lemon juice. Boil ten minutes. Remove from the fire and mix with a tablespoonful of butter while warm. The lemon rind can be grated and added to the sauce instead of boiling the rind. This is good for steamed puddings. The yolk of an egg may be added.

CHERRY SAUCE.

Remove the stones and steep the cherries in water with a stick of cinnamon. Add a little sugar and thicken with cornstarch or arrowroot. Strain or leave the cherries in it.

DRIED CHERRY SAUCE.

Soak the cherries and prepare as the foregoing. Strain, if desired.

WHITE WINE SAUCE.

Mix a teaspoonful of flour with two tablespoonsful of sugar, a little cinnamon, and ten ounces of wine. Then beat up four eggs, mix with the wine and beat over a hot fire with an egg beater until it foams. (It must not boil.) Then pour into a large dish and beat until nearly cold. Serve with steamed puddings.

RED WINE SAUCE.

Prepare like white wine sauce. Add a little more sugar, and a teaspoonful of brandy, if desired.

SALAD DRESSINGS FOR MEATS, CEREALS, FISH, VEGETABLES AND FRUITS.

They can be prepared from oil, butter, eggs, cream or nut butter. Dressings prepared from nut butter are especially good during the summer months. They can be prepared by making a plain butter sauce with flour and water, and adding nut butter before serving, or by diluting nut butter with water to the desired consistency. They may be flavored with orange or lemon juice. If a sweet flavor is desired, boil a little water with sugar, then add the juice of lemon or oranges and mix with nut butter. Serve hot or cold.

FRENCH DRESSING.

Mix three tablespoonsful of olive oil with one of vinegar, or with the juice of one lemon and one grated onion. To this may be added sugar, pepper, salt, parsley or mustard, if desired. The proportion of oil and vinegar may be changed according to the taste. For fruit salads, lemon should always be used instead of vinegar. For raw vegetables, the dressing should not be poured over the salad until ready to serve.

MAYONNAISE DRESSING. No. 1.

Put into a high narrow bowl the yolk of an egg and one whole egg, a tablespoonful of flour, one of olive oil, one of vinegar, and a little mustard; beat with an egg-beater about five minutes, or until it becomes thick, adding slowly one cup of cottonseed or olive oil while beating it. Flavor with lemon juice, onion and salt, to suit the taste. Keep on ice.

MAYONNAISE DRESSING. No. 2.

Stir one or several yolks of eggs and mustard with a fork on a soup plate for several minutes. Slowly add some olive oil, and if it becomes too thick, add lemon juice, then salt, sugar and onion, if desired. Keep on ice.

MAYONNAISE DRESSING. No. 3.

Make dressing number two. Add salt and sugar to suit the taste, and one cup of thick cream. Keep on ice.

MAYONNAISE DRESSING. No. 4.

Take the yolks of three hard boiled eggs and one raw yolk. Stir as smooth as butter, with one teaspoonful of mustard, one of sugar, one of grated onion, a little salt and pepper, the juice of a lemon or some good vinegar, then add slowly one-half or one cupful of olive oil. If the dressing is too thick add some cold veal jelly until it has the right consistency. Keep on ice.

MAYONNAISE DRESSING. No. 5.

Grate one medium sized cold boiled potato, stir one or two hard boiled eggs through a strainer and mix with the potato. Add the yolk of one or more eggs, stir well, then slowly add some olive oil, mix with lemon juice or vinegar, and flavor.

MAYONNAISE DRESSING. No. 6.

Cream one-fourth of a pound of butter, add the yolk of one raw egg, and the finely grated yolks of two hard boiled eggs. Mix well, and add finely chopped parsley, onion, a little mace and some lemon juice. Serve with cold meat or fish, or spread on bread.

MAYONNAISE DRESSING. No. 7.

Prepare butter and eggs as directed in number six, adding finely chopped boiled ham, sardellen, anchovies or well soaked salt herring. Eat with cold meat, or spread on bread.

MAYONNAISE DRESSING. No. 8. (BOILED.)

Mix two tablespoonsful of flour with five yolks of eggs, then add a half cup of butter or a cup of cream, a little salt and pepper, (sugar if desired), three to four tablespoonsful of vinegar and one to two cups of soup stock. Pour into a double boiler and stir over a hot fire until thick, then remove and stir until cool. Finely chopped parsley, capers, pickles, or olives may be added. If lemon is desired, use half the amount of vinegar while boiling, and add the lemon juice after it has been removed from the fire.

MAYONNAISE DRESSING. No. 9. (BOILED.)

Boil a small veal bone in three or four pints of water, adding salt, several onions, whole pepper and some spiced herbs. When, nearly done, add three to six tablespoonsful of good vinegar, strain and add the yolks of several eggs. Stir until cool, and place on ice. Serve with cold fish or meat. If the sweet-sour taste is liked, a little sugar may be added to the broth while boiling. Ripe olives are also a good addition.

SYRUP DRESSING. No. 1.

Add the juice of one lemon, orange, or grapefruit, to one-half cup of maple or table syrup. Mix well and serve with pancakes. This is more nourishing and wholesome than pure sweets. Do not prepare more than enough for one meal at a time.

SYRUP DRESSING. No. 2.

Let a half cup of syrup and a small tablespoonful of vinegar come to a boil. Add one finely chopped onion. Remove from the fire and cool, adding the desired amount of oil, and mixing well. This is good for lettuce and watercress. Serve with pancakes, meats, fish, or baked rolled oats, or with rye or wheat. If lemons or oranges are used in place of vinegar, do not allow the latter to boil. Prepare fresh for each meal. Do not use vinegar or onions with fancy fruits.

CHAPTER VIII.

SALADS.

Salads consisting of =mixed= nuts or =mixed= boiled vegetables are not wholesome for delicate people.

LETTUCE SALAD.

Lettuce should be kept in a cool, dry place and not left in water longer than 15 minutes. It may be served alone as a salad mixed with French dressing or served in combination with fruits, starchy foods or other vegetables, and eaten in addition to meats and fish or cheese. Watercress salad can be prepared and served in the same way as lettuce salad.

MEAT SALAD.

Use any kind of cold left-over meat, cut into small pieces or chopped fine, mixed with dressing and garnished with green leaves.

FISH SALAD.

Cut some left-over fish in small pieces, mix with dressing and garnish with leaves.

CUCUMBER SALAD.

Peel and slice the cucumbers thin and pour French or mayonnaise dressing over them. They may be combined with lettuce, tomatoes, chopped parsley or onions.

TOMATO SALAD.

Prepare and mix like cucumber salad. Serve with French or mayonnaise dressing.

BOILED VEGETABLE SALAD.

Use left-over asparagus, string beans, cow beans, lima beans, green peas or cauliflower. Pour over them French dressing half an hour before serving, adding lettuce and mayonnaise dressing when ready to serve.

SPINACH SALAD.

Take some fresh leaves of raw spinach or use cold boiled spinach, and mix with French dressing.

CHEESE SALAD.

Chop up some tart apples, arrange lettuce in a salad bowl, pour in the apples, and sprinkle over it grated Swiss cheese.

NUT SALAD.

Chop or grind in a nut grinder some almonds or walnuts. Arrange lettuce and chopped apples in a salad bowl, sprinkle the nuts over it, and serve with celery and raisins. The French dressing may be omitted.

EGG SALAD.

Arrange lettuce in a salad bowl. Cut up hard boiled eggs, pour over them French or mayonnaise dressing. Caper or olives may be added.

ANCHOVY BUTTER.

Soak the fish for 20 minutes or longer, wash, clean, and chop fine. Add several finely chopped yolks of hard boiled eggs, and parsley, if desired. Cream some sweet butter and mix with the chopped fish and eggs. Spread on stale slices of bread. Serve with lettuce or celery, and hard boiled eggs. Apples and tomatoes combine well with all kinds of fish.

The anchovy butter may be mixed with mayonnaise dressing and served in egg shells cut in halves.

EMPIRE SALAD.

Ingredients: One large well soaked salt herring, two raw apples, two cold boiled potatoes, one cup of cold boiled chopped veal or beef, six hard boiled eggs, three boiled beets, three stalks of celery or one boiled celery root, onions, parsley, and two tablespoonsful of mustard. Chop fine each of the ingredients separately. Set apart three tablespoonsful of chopped whites of eggs, yolks of eggs, beets and parsley. Mix all the other ingredients well and add about one cup of mayonnaise dressing. Put the salad on a platter or into a large glass dish; garnish with lettuce and olives and make designs of green, red, white, and yellow with left-over ingredients. Let the salad stand in a cold place for several hours before serving. If it stands too long, the taste of the herring becomes too strong.

DRIED FISH SALAD.

Soak in warm water for 15 minutes some dried smoked herring or salmon. Cut in small pieces, mix with mayonnaise or French dressing, and garnish with lettuce. The fish may be left whole and served with apple salad.

CABBAGE SALAD.

Use the innermost part of a head of cabbage. Cut and chop very fine, add lemon and olive oil, and mix with mayonnaise dressing. A cold grated potato may be added for those who have difficulty in digesting cabbage.

TOMATO AND WATERCRESS SALAD.

Carefully wash some watercress, dry, and mix with equal parts of sliced tomatoes. Use French or mayonnaise dressing.

DANDELION SALAD.

Carefully wash and mix with finely cut green onions and French dressing.

YELLOW DOCK SALAD OR SOUR GRASS.

Wash and serve plain or mix with lemon and olive oil.

HERRING SALAD. No. 1.

Remove the skin and bones from a smoked herring. Cut the fish into small pieces, and mix with thinly sliced apples or tomatoes, and salad dressing. Garnish with lettuce. Serve with soda crackers or with wheat or rye bread.

CELERY SALAD.

Cut the tender white stalks into small pieces. Add chopped apples and nuts or salad dressing.

ANCHOVY SALAD.

Soak the fish for half an hour, remove the bones, fins, and head. Chop up green onions and parsley. Cut tomatoes or apples into small pieces and mix with equal parts of fish, add the onions and mix with French or mayonnaise dressing. Lettuce and hard boiled eggs cut in halves may be mixed or served with it.

HERRING SALAD. No. 2.

Prepare the same as anchovy salad. Use pickled herring.

RADISH SALAD. No. 1.

Wash and slice some radishes, mix with chopped onions, finely cut chipped beef or any left-over meat or ham. Garnish with lettuce, and serve with French or mayonnaise dressing.

OLIVE SALAD.

Stone and slice some ripe olives. Mix with equal parts of thinly sliced tomatoes and French or mayonnaise dressing. Serve on lettuce.

RHUBARB SALAD.

Wash the rhubarb, cut the red part of it into one inch pieces and mix with mayonnaise dressing.

APPLE SALAD.

Arrange some lettuce in a salad bowl, add chopped or sliced apples, onions and parsley, and mix with French or mayonnaise dressing. Grapenuts or ryenuts may be sprinkled over it. Serve with fish, meat or cheese.

ASPARAGUS SALAD.

Cut off the tips of raw asparagus, arrange some lettuce or watercress in a salad bowl, and mix with French or mayonnaise dressing. Sliced tomatoes may be added. Boiled asparagus may be prepared in the same way.

MUSHROOM SALAD.

Arrange some lettuce or watercress in a dish, select fresh mushrooms, wash and mix with French dressing, and pour over the green leaves.

BANANA SALAD.

Arrange lettuce and sliced bananas in a salad bowl, adding a French dressing of lemon and olive oil. Ryenuts or grapenuts may be sprinkled over it. Scrape off the inside of the skin of the bananas, and mix with it.

ORANGE SALAD.

Peel some oranges, slice them crossways, remove the seeds, put into a bowl and grate some of the orange rind over them. Serve plain or with lettuce, and pour a French dressing of lemon and olive oil over it.

PINEAPPLE SALAD.

Peel and slice crossways, serve with lettuce and lemon or with sweet cream.

PINEAPPLE AND APPLE SALAD.

Mix equal parts of sliced apples and pineapples. Serve like the foregoing or with nuts.

PINEAPPLE AND ORANGE SALAD.

Mix equal parts of sliced oranges and pineapples. Serve like the foregoing.

APPLE AND BANANA SALAD.

Prepare and serve like the foregoing, with cream or nuts.

ORANGE AND BANANA SALAD.

Scrape off the bitter pulp of the inside of the skin of the banana, mix with sliced oranges and bananas, and serve like the foregoing.

FRUIT SALAD IN GELATINE.

Prepare some lemon or orange gelatine. Let cool and pour over the sliced fruit. Set on ice and serve plain or with cream.

CRANBERRY AND CELERY SALAD.

Wash and cut some celery the size of cranberries. Mix with an equal amount of cranberries, and serve plain or with lemon and olive oil.

PEACH SALAD.

Wash and slice some peaches. Serve with cream or lettuce, lemon, and olive oil. Fried beachnut bacon and shredded, puffed or raw rolled wheat are a good addition, if lemon and oil is used.

APRICOT SALAD.

Prepare and serve in the same manner as peach salad.

CRANBERRY AND BANANA SALAD.

Cook some cranberries, strain, and thicken with a little cornstarch. Cool and pour over sliced bananas. Serve with raw celery.

CRANBERRY AND PEAR SALAD.

Combine like the foregoing or use baked pears. Raw cranberries with raw pears and celery is also good.

BANANA AND GRAPE SALAD.

Slice some bananas and mix with an equal quantity of green grapes. Garnish with lettuce, and add lemon and olive oil, if desired.

RADISH SALAD. No. 2.

Mix some chopped or sliced radishes with French or mayonnaise dressing, and add lettuce or celery. Serve for breakfast with whole wheat bread and butter, or with raw wheat flakes.

BEET SALAD.

Mix some left-over sliced beets with French dressing. Serve with cold fat pork or bacon for breakfast or dinner. Celery and whole wheat or black toast with butter make a good combination in place of the meat.

MIXED SPINACH SALAD.

Wash some fresh tender spinach leaves. Cut fine and mix with French dressing, mint and onions. Tomatoes may be added. Serve with hard boiled eggs.

CARROT SALAD.

Grind, chop or slice the carrots and mix with French dressing. Add chopped parsley, lettuce or celery. Serve with rye or wheat flakes or with bacon.

RAW CORN.

Remove the husks from fresh raw corn and place it in cold salted water for 15 minutes. Cut from the cob with a sharp knife, and serve plain or with tomatoes, lettuce and French dressing. This affords a perfect meal for dinner during the summer.

CELERY ROOT SALAD.

Scrub the roots with a brush and boil in the skins until tender. Peel, cut into slices, heap in a high bowl, and pour a little diluted vinegar or lemon juice over them. Let stand for 15 minutes, pour off the acid and mix with French or mayonnaise dressing. This is good for diabetic patients.

CEREAL SALAD. No. 1.

Mix a cupful of raw rolled wheat, oats or rye with a cup of finely grated or chopped carrots. Add a few drops of lemon or orange juice, and a little olive oil. Lettuce, celery or parsley may be mixed or eaten with it.

CEREAL SALAD. No. 2.

Wash and chop lettuce or celery, and apples. Mix with French or mayonnaise dressing. Then add an equal amount of rolled raw cereals and serve. Parsley or watercress may be added. A syrup dressing or onions combine well with it. Peaches and apricots may be used in place of apples and carrots. Onions should not be used with peaches or apricots.

CHAPTER IX.

GELATINES AND TOASTS.

GELATINE PREPARATIONS.

Gelatine is a valuable food for the sick. The nutritive value of gelatine is under-estimated. While it alone cannot sustain life, it is superior to beef tea, and if eaten with other articles which supply the elements which it lacks, it can partially take the place of meat and other nitrogenous foods for sick people and for people of sedentary habits. For people who do hard labor gelatine is of little

value.

FRUIT GELATINE.

To prepare fruit gelatine the acid and super-acid fruits are best, and =no more sugar= should be used than is necessary. Gelatine preparations must be kept on ice, or in a very cold place, and not be prepared in large quantities, as they easily putrefy. For the sick and for children, it should not stand longer than twenty-four hours, and it should not be kept in metallic dishes. The best time to serve gelatine is for the evening meal. It may be served with sterilized cream, and zwieback or wafers.

Prepare some gelatine according to directions on package. Add to it juice from preserved apples, cherries, raspberries, strawberries or currants.

GELATINE PUDDING MADE WITH SOUR MILK.

Prepare some white gelatine with two cups of water. Take twice the amount of gelatine directed and add one-half cup of sugar. Remove from the fire, cool slightly, then add two cups of sour milk which has been beaten, and mix all well. Flavor and set in a cool place. Serve with sweet cream and zwieback.

WHIPPED SOUR MILK.

Beat one quart of thick, sour milk with an egg beater for 10 minutes. Serve with zwieback in soup plates. Three-fifths tablespoonful of powdered sugar and a little cinnamon may be added, if it is agreeable.

Whipped sour cream may be prepared the same as sour milk.

WHIPPED SWEET CREAM.

Whip one quart of sweet, thick cream with two-fifths of a tablespoonful of powdered sugar, add a little vanilla, if desired. Serve with fruit gelatines or ground white figs, stewed prunes, baked apples or raw fruits, such as peaches, strawberries, raspberries or bananas.

BANANA GELATINE.

Prepare some gelatine with orange, cranberry or lemon juice. When nearly cold, cut up some bananas and mix with the gelatine. Flavor and set on ice, serve with whipped or sterilized cream.

PINEAPPLE GELATINE.

Prepare some gelatine with lemon or orange juice. When nearly cold, add some fresh or canned pineapple. Serve with whipped or sterilized cream, and zwieback.

BEER GELATINE.

Prepare with rye beer in the same way as the fruit juice. Take one pint of beer to one pint of water. Use the imported root beer.

BLANC MANGE

Prepare some gelatine with milk, sugar and a little salt. Remove from the fire, set on ice, and mix with boiled custard when cool. Flavor with vanilla or bitter almond.

CALVES' FOOT JELLY.

Wash a calf's foot several times in hot and cold water. Bring to a boil and pour off the first water. Bring to a boil again, add some salt, and cook from two to three hours. Strain through a cheese-cloth. The next day remove the fat, bring to a boil again, add one to two cups of wine, the juice and rind of several lemons or oranges, and sufficient sugar to counteract the sour taste. Pour into a dish which has been oiled, and set on ice. It may be served with whipped cream or the beaten whites of eggs, and shredded wheat or zwieback.

SNOW PUDDING.

Soak some gelatine according to directions. Add a pint of boiling water, some tart fruit juice and the necessary amount of sugar. Let it come to a boil, stir and strain, and let stand in a cold place for several hours. When it begins to set, beat up the whites of two eggs with a little salt or lemon juice, and sugar, and mix with the gelatine. Pour into molds and set on ice. Serve with whipped cream or custard sauce.

RICE GELATINE.

Boil one cup of rice in about three pints of water with a little salt, for 40 minutes. Soak gelatine, half the amount directed on the package, and when soft, add the strained rice water to it, bring to a boil, sweeten to taste, and put into molds or cups. Serve with whipped or sterilized cream and zwieback. Merk's sugar of milk should be used if prepared for the sick.

TOMATO GELATINE.

Strain a can of tomatoes, mix with soaked gelatine and bring to the boiling point, adding lemon or salt, if desired. Put into molds and set in a cool place. Serve with cold meat or fish, olives and greens.

BARLEY GELATINE.

Prepare like rice gelatine. Half rice and half barley may be used. Dried raisins or currants may be added, if desired.

WHEAT GELATINE.

Cook three tablespoonsful of Cream of Wheat with two or three pints of water and some salt. Boil 20 to 30 minutes. Strain and prepare like rice gelatine. Flavor according to desire. If the rind of a lemon is used, boil with the gelatine. This gives it an excellent flavor.

BUCKWHEAT GELATINE.

Wash the buckwheat groats several times with cold water, then soak or put into boiling water at once. Boil from 30 to 40 minutes. Flavor to taste. Finish like the foregoing. It is very good during the winter.

OAT GELATINE.

Wash and soak one cupful of steel cut oats in two quarts of water. Add some bran, if desired. Boil 30 to 40 minutes with a little salt, and drain and strain. Do not press the starch through. Prepare like rice gelatine.

BRAN GELATINE.

Soak one cupful of bran in three pints of soft water for several hours, or over night; one-half cupful of rylax or black crusts may be added. Bring to a boil slowly and let simmer for 15 or 20 minutes. Soak some gelatine, a little less than the directions call for. Add the strained bran juice and a few dried currants which have been soaked in boiling water. If sugar is desired, add a small tablespoonful. Let it come almost to the boiling point, add salt, and put into molds. Serve plain or with sterilized cold cream.

RYE GELATINE.

Prepare like bran gelatine, using less bran. Toast thoroughly brown three or four slices of stale pompernickel and soak with the bran. If boiling water is used for soaking, less time will be required for it. A stick of cinnamon gives the rye a good flavor. Rylax may be used in place of pompernickel.

PEA GELATINE.

Wash and soak over night one cupful of whole dried green peas in three pints of soft water. The next day let them slowly come to a boil and add cut-up onions, carrots, celery or parsley, and salt if desired. Simmer slowly in earthen ware for one hour at least. Strain and prepare with gelatine as directed in the foregoing. Do not press the peas hard through a strainer; allow only a little pulp in the broth. Serve with zwieback spread with almond butter or with a little finely ground walnut meat.

COFFEE GELATINE.

Pour two pints of boiling water on four or five tablespoonsful of coarsely ground coffee. Steep (not boil) for five minutes, then strain. Soak some gelatine according to directions on package. When soft, mix with the hot coffee, add sugar to suit the taste, and let it come almost to the boiling point. Mix well and pour into molds or cups, which have been rinsed in cold water. Serve with whipped or sterilized cream, and zwieback or Nabisco.

CEREAL COFFEE GELATINE.

Prepare some strong cereal coffee according to directions on package. Prepare like the above. A small amount of coffee may be mixed with the cereal coffee, just before removing from the fire.

CHOCOLATE GELATINE.

Grate eight tablespoonsful of chocolate, put into a pint of cold sweet milk, bring to a boil, and add a few tablespoonsful of sugar. Soak some gelatine, and when soft, add one pint of hot milk and heat to the boiling point. Then mix with the hot milk containing the chocolate, pour into molds or cups, and set in a cool place. Serve with cream, zwieback or Nabisco.

For invalids, it is better to prepare the gelatine and chocolate in water instead of milk, and serve with whipped or sterilized cream.

WINE GELATINE.

Use part wine, sherry or claret. Prepare like fruit gelatine. Serve with cream or custard sauce, and wafers.

BREAD GELATINE.

Toast two slices of white and two slices of black bread. Pour three pints of boiling water on them. Simmer for half an hour. Soak some gelatine, and when dissolved, strain the bread-water and add to the gelatine. Bring to a boil, add sugar, and flavor with a little wine or lemon juice. Pour it into molds and cool.

BEAN GELATINE.

Prepare like pea gelatine with or without flavoring. Lima beans or horse beans are best in summer; small white beans in the fall; red, brown, or black beans are best in cold weather, as they are richer in iron and minerals. They can all be served plain with toast or zwieback and butter, cream or nut preparations. Black toast or crusts combine better with lima and white beans than white toast or bread.

LENTIL GELATINE.

Prepare like the foregoing. Flavor richly with onions. Serve with white toast.

TOASTS.

WATER TOAST.

Use zwieback, or toast some stale white bread over the open fire. Lay on a plate and pour over it quickly boiling water, slightly salted, and drain off at once. Serve plain, or spread with sweet butter, or the yolk of an egg.

TOMATO TOAST.

Prepare like the foregoing, spreading with tomato puree in place of butter. Drink with it rich fresh milk. This is excellent for people who have difficulty in digesting milk. Strained hot tomato juice may be used in place of water.

BARLEY TOAST.

Prepare like tomato toast. Use thick, barley jelly prepared from pearl barley, or soften the toast with barley water.

RICE TOAST.

Use thick rice jelly prepared from Carolina rice. Flavor with cinnamon, if desired.

RYE OR BRAN TOAST.

Make a strong tea from toasted black bread and bran, and prepare like the foregoing.

PRUNE TOAST.

Soften some black or white toast with boiling water, and add a little salt. Spread with thick prune juice. Sterilized cream may be added.

APRICOT TOAST.

Prepare the same as prune toast. Add cream or a piece of butter and the yolk of an egg.

APPLE TOAST.

Use thick apple sauce. Prepare the same as apricot toast. The four last recipes are excellent for constipation.

MILK TOAST.

Scald some fresh milk. Add a stick of cinnamon, if desired. Pour over white or black toast.

CREAM TOAST. No. 1.

Prepare like water toast. Bring some fresh cream to a boil with a stick of cinnamon. Add when the toast is soft. Use black or white toast.

CREAM TOAST. No. 2.

Prepare a white sauce from butter, salt, flour and hot water, as directed in “Sauces.” Add one-fourth of a cup of hot cream and pour over black toast, which has been softened with one-half cup of hot water.

CREAM TOAST. No. 3.

Use sweet whey in place of hot water, and prepare as No. 2. The cream may be omitted.

CELERY TOAST.

Cut some celery and cook until tender. Soften the toast with the celery water. Prepare a plain butter sauce and add cream, if desired. Mix with the celery and pour over the toast.

CLAM TOAST. No. 1.

Soften the toast with hot clam broth and strain, if desired. Mix the remainder with hot cream and pour over the toast.

CLAM TOAST. No. 2.

Soften the toast with clam broth. Prepare a white sauce from the remainder, add hot cream and pour over the toast.

OYSTER TOAST.

Prepare like the clam toast, with or without cream.

SPINACH TOAST.

Cut off the stems and select only fresh tender leaves. Cook and chop as fine as possible, flavoring with butter and lemon juice. Soften some black or white toast with broth or spinach water, and add the spinach. Serve with hard boiled eggs for dinner. If it is desired for supper, and if the patient’s stomach is delicate, use only the hard yolks. Fried beachnut bacon may be added. If the flavor of onion is desired, remove the onion before serving. This is good for constipation.

EGG TOAST. No. 1.

Beat one egg with three tablespoonsful of water or soup stock, and a little salt. Let the toast soften in it and fry to a golden brown in one-half butter and half vegetable fat or oil.

EGG TOAST. No. 2.

Use cream or unsweetened condensed milk. Beat up with eggs, salt and cinnamon, and prepare like the foregoing. This is good for diabetic patients.

CHAPTER X.

FRUITS, PUDDINGS AND GRUELS.

STERILIZED DRIED FRUITS.

Place some dried cherries, apricots, currants or prunes in a Mason jar. Fill to the top, cover with water, and let stand over night. The next day set the jar into a water bath, heat to the boiling point, then cool. Enough can be prepared to last for several days. The juice may be used again for soaking, or it can be used for fruit gruels.

SOAKED FRUIT. No. 1.

Wash some dried fruit, put into a bowl, pour over some hot or cold water, place over it a little saucer with a weight upon it; in this way it requires less water; let stand over night. It is ready for use the next morning, and may be mixed with boiled cereals in place of sugar.

SOAKED FRUIT. No. 2.

Place some dried fruit in a bowl, pour over it some hot cereal coffee. Use in the same way as number one. This is excellent for people suffering with fermentation of the stomach. The cereal coffee acts as a preservative.

FIG BUTTER. No. 1.

Wash some dried figs, dry them; then cut into small pieces, and grind on a nut grinder. Mix with one-fourth (in quantity) of ryenuts. Serve with whipped or sterilized cream.

FIG BUTTER. No. 2.

Prepare as the foregoing. Mix with about one-third or one-fourth of ground nuts, also with ryenuts, if desired. Serve with lettuce.

RAISIN OR CURRANT BUTTER.

Prepare like figs. Mix with ground nuts. Serve with lettuce or with chopped apples.

GROUND DATES.

Remove the stones and prepare as above. Mix with ryenuts or orange juice. Serve with lettuce and sliced bananas or nuts.

GROUND DRIED PRUNES.

Prepare like figs. Mix with ryenuts. Serve with cream or with nuts and lettuce.

BAKED APPLES.

Wash and remove the core; then place in a baking tin, stem end down; pour over some water and a little sugar, if desired, bake in a moderate oven until tender. Let cool and serve plain with butter and bread or with whipped or sterilized cream.

BAKED PEACHES.

Prepare the same as baked apples, and serve with cream.

AMBROSIA.

Mash baked apples very fine and rub through a colander. Mix with soaked or stewed raisins, if desired. Serve in place of apple sauce with beaten whites of egg or whipped cream and zwieback.

BAKED APPLES IN GELATINE.

Prepare in the usual way, pour some fruit or rye gelatine over them.

APPLE SAUCE. No. 1.

Wash some tart apples, cut into four pieces and remove the seeds; steep with a little water and sugar until tender. Then mash fine with a potato masher and run through a colander. Add a piece of butter while warm. Apple sauce prepared in this way is more wholesome than prepared from apples that have been peeled.

APPLE SAUCE. No. 2.

Soak some dried apples over night, steep for 30 or 40 minutes with a piece of cinnamon and a little sugar, and mash fine with a potato masher. Add a piece of butter. Let cool and serve with fish, eggs, boiled beef or cheese.

APPLE SNOW.

Prepare some apple sauce from dried or fresh apples, run through a colander; when cool, mix with the snow of whites of eggs. Serve with zwieback.

APRICOT SNOW.

Prepare same as apple snow.

APRICOT SAUCE.

Wash some dried apricots thoroughly, cut into small pieces, soak over night, then simmer slowly until soft. Run through a colander and add a piece of fresh butter while warm. Serve with French toast, corn bread, corn cakes, steamed puddings or omelet; also good with fish and meats, especially fat meats.

GOOSEBERRY COMPOTE.

Remove the stems, wash the berries and pour some boiling water on them. Let stand 5 minutes; then pour off the water and add fresh boiling water, a stick of cinnamon and the necessary amount of sugar. Thicken with cornstarch. Serve with unleavened pancakes.

GOOSEBERRY PUDDING.

Prepare the gooseberries in the same manner as for compot, but use more water. When done, strain and thicken with cornstarch. Let boil 10 to 15 minutes. Serve hot or cold with cream.

STEWED BLACKBERRIES.

Wash a pint of blackberries, put on to cook with about two pints of boiling water and a stick of cinnamon. Let simmer slowly and add a few tablespoons of sugar. When nearly done thicken with a little cornstarch. Cool and serve with milk rice, custard or pancakes.

STEWED HUCKLEBERRIES.

Prepare the same as stewed blackberries. Strain, if desired.

BAKED APPLES IN OIL.

Wash some tart apples, wipe and core them. Have some vegetable oil, goose grease or lard boiling hot, drop in the apples and cook until tender. Let cool and reheat when needed.

BEER GRUEL.

Soak a half cup of instantaneous tapioca with a half cup of water for 10 minutes. Bring a cup of water and a cup of beer with a stick of cinnamon to a boil, stir in the tapioca, let boil to minutes, add sugar and salt. Then remove from the fire, add three to five tablespoonsful of fresh hot cream and serve. A piece of butter and the yolk of an egg can serve as substitute for the cream. Serve with zwieback.

APPLE TAPIOCA.

Prepare as the foregoing, from apple cider or unfermented apple juice. Serve with cream or with butter and the yolk of an egg. Hot or cold. Serve with zwieback or wafers.

TOMATO TAPIOCA.

Use one cup of strained tomato juice to one of water. Prepare as the above. Serve with cream and zwieback.

BERRY TAPIOCA.

Cook one quart of raspberries or blackberries with two quarts of water, a piece of cinnamon, add three-fourths to one cup of sugar, let boil slowly, then, strain and cool. Reheat and prepare with instantaneous tapioca. Pour on a soup plate, pour sterilized cream over it. In cold weather, the cream as well as the tapioca should be served warm.

RHUBARB PUDDING.

Wash the stalks and cut off the green end. Cut the remainder in small pieces and steep in earthenware with a stick of cinnamon. When, tender, strain and add the necessary amount of sugar. Dissolve some cornstarch, arrowroot or agar-agar with cold water and stir into the fruit juice. Let boil 10 minutes and serve warm on soup-plates with sterilized cream or put into molds and cool. If it is eaten warm, it is preferable to let the fruit juice cool first, then reheat and add the thickening.

APPLE PUDDING.

Save all the peeling from several days; add a few whole apples. Cook with water, strain and prepare like rhubarb pudding.

CURRANT, RASPBERRY OR PEACH PUDDING.

Prepare the same as the foregoing. If peaches or peach skins are used, do not press much of the pulp through. It is better to use more peeling than whole fruits. In serving peach or apple salad, the peelings can be saved from a day or two and preserved by stewing them in a little water until ready for use.

LEMON FILLING FOR PIE.

Stir the yolks of three eggs with one-half cup of sugar, add the grated rind and juice of two lemons or one lemon and one orange, then add two tablespoons of cornstarch, one of butter and one and one-half cup of hot water. Stir in a double boiler over the fire until it is thick. Then pour it into the baked crust. Beat the whites with a tablespoon of sugar and a little lemon juice. Put over the top and brown in the oven.

STRAWBERRIES WITH WHIPPED CREAM.

Select fresh ripe berries and wash. Put the desired amount on flat medium-sized plates. Beat up some cream with the whites of several eggs and a little powdered sugar. Cover the berries with the cream and serve with wafers or triscuit.

PEACHES AND PEARS WITH WHIPPED CREAM.

Peel and slice them. Prepare and serve the same as the foregoing. These dishes are not good for delicate stomachs.

PLAIN JUNKET.

Warm one pint of milk to blood heat, flavor as desired; stir in one junket tablet which has been dissolved in a little water and pour into a dish; set on ice. Serve with cranberry or prune sauce and wafers.

WINE GRUEL.

Bring equal parts of white or red wine and water to a boil, flavor with lemon rind or cinnamon, add sugar, thicken with instantaneous tapioca or with potato flour. Serve plain or add a piece of butter and the yolk of an egg.

WINE GRUEL OF PORT OR SHERRY.

Soak some plain sago or tapioca for about three hours, then pour into boiling water, add sugar, lemon rind, and a pinch of salt. When almost done, add port or sherry (one to three ounces to one person). Serve plain, or with butter and the yolk of an egg.

WINE GRUEL OF RED CLARET.

Bring equal parts of wine and water to a boil, thicken with potato flour or instantaneous tapioca, add sugar and a little salt, add a small amount of preserved raspberries or strawberries, jam or jellies, or sliced pineapple. The whites of several eggs beaten to a snow with a little salt may be mixed with it before serving. Zwieback or wafers is a good addition.

RICE GRUEL. No. 1.

Mix two to three tablespoonsful of rice flour with a little cold water, add to it a pint of boiling water, two level tablespoonsful of sugar of milk, salt to taste, boil fifteen to twenty minutes. Put on a soup plate, pour hot or cold sterilized cream over it.

RICE GRUEL. No. 2.

Prepare as number one. After removing from the fire, add a piece of butter, and the yolk of an egg, mix thoroughly, then put on a soup plate. Serve with or without cream.

CHOCOLATE CORNSTARCH.

Bring a pint of water to a boil, mix with two tablespoonsful of chocolate, let boil two minutes, then thicken with two tablespoons of cornstarch. Flavor with salt and vanilla. Pour on a soup plate. Serve with sterilized cream, hot or cold.

BOILED CUSTARD.

Bring one pint of sweet cream or rich milk and one pint of water to a boil with a piece of vanilla. Then mix one tablespoonful of cornstarch with a little cold water and three yolks of eggs, two tablespoonsful of sugar, and a little salt. Add all to the boiling milk, stir over the fire or in a double boiler until it thickens. Remove and beat until nearly cold. Put on ice. It may be served with zwieback and fruit juice or with fresh berries. For dyspeptics, it is better if prepared with water and butter instead of milk and served with sterilized cream.

BLACKBERRY SAGO.

Boil one quart of blackberries with about two quarts of water and some sugar very slowly, then strain and cool, bring to a boil again, prepare with instantaneous tapioca or plain sago. The latter must be well soaked. Serve warm with zwieback or wafers and sweet butter.

APPLE SAGO.

Boil tart apples with the skin in plenty of water; when tender strain and cool. Reheat, flavor with cinnamon and sugar. Prepare with instantaneous tapioca or plain sago. After removing from the fire add orange juice, lemon, butter and the yolk of an egg or serve with sterilized cream.

ONION GRUEL. No. 1.

Cut fine three or four onions, stew them in a quart of water very slowly and keep them well covered. When tender strain; heat butter or olive oil and thicken with mixed flour; add the onion broth slowly, let boil a few minutes. Flavor with salt and lemon. One-half soup stock and one-half onion broth may be used. Cream can be added if desired.

ONION GRUEL. No. 2.

Put one-half of a cup of barley to soak, boil with four dried or green onions. Add salt, and strain.

BREAD GRUEL. No. 1. (WITH BARLEY.)

Soak and boil one-half cup of barley with salt in three pints of water, very tender, until there remains about a cup of liquid. Strain this. Then, take some French bread or soda crackers, pour sufficient boiling water and a tablespoonful of milk sugar or cane sugar on it, let stand until it is perfectly soft, or until the water is all soaked into the bread. Then add the cup of barley water, let all boil for a few minutes or until bread and barley are well united. It may be strained, if desired.

BREAD GRUEL. No. 2. (WITH BRAN.)

Take a cup of select bran, simmer slowly with two pints of water and a little salt, while boiling, add three tablespoonsful of milk sugar or a teaspoonful of can sugar. Strain, finish like bread gruel number one. Add dried soaked sweet fruit, if desired.

BREAD GRUEL. No. 3. (WITH OATS AND BRAN.)

Take one-third of steel cut oats and two-thirds of bran. Prepare like bread gruel number one. Add sweet fruits, if desired.

OATMEAL GRUEL. (WITH BRAN.)

Soak a half cup of steel cut oats or rolled oats and a cup of bran. Put on to boil with three pints of cold or boiling water and salt. Let boil slowly for three-fourths of an hour. Strain, add butter and serve. This is excellent for nursing mothers. Use more water if it is desired thin.

CORNMEAL GRUEL.

Put one-half to three-fourths of a cup of corn meal to boil with three pints of boiling water and some salt. Let boil fast during the first ten minutes, then set aside and boil slowly for twenty or thirty minutes. Remove from the fire, add a small tablespoonful of butter, the yolk of an egg and a few drops of lemon; the rind of the lemon may be grated over it. Mix all well, pour on a soup plate, eat plain or with hot sterilized cream. The butter, egg and lemon, may be left out, and cream added only.

CODFISH GRUEL.

Soak two tablespoonsful of shredded codfish for twenty minutes, change the water several times. Add boiling water and flavor with onion. Heat butter or olive oil, thicken with mixed flour, add the onion water slowly, at last the soaked codfish. Let all boil a few minutes. Chopped parsley and hot cream may be added, if desired. Serve with toast.

BARLEY GRUEL.

Soak a half cup of pearl barley, put on to boil with three pints of water, add salt and three tablespoonsful of milk sugar. Let boil slowly for one hour, then strain. Heat a tablespoonful of butter, thicken with mixed flour, add the barley gruel gradually, let all boil a few minutes, then serve.

WHEAT GRUEL.

Put two to three tablespoons of cream of wheat or farina into a saucepan. Add a pint of boiling water, a pinch of salt, and a tablespoon of milk sugar. Let boil half an hour. Remove from the fire and mix with a teaspoon of butter or two to three ounces of hot cream. Dried soaked raisins or currants may be added.

GLUTEN GRUEL.

Prepare as directed on package. Add cream or butter and the yolk of an egg.

RAW CEREAL GRUEL.

Soak one-half to one-third cup of flaked raw cereal with a cup or more of warm salted water. Let stand for several hours or over night in a warm place. Serve plain or with sweet dried fruits and fresh cream.

MIXED FLOUR GRUEL. No. 1.

Mix two tablespoonsful of mixed flour with a little cold water, add two to three cups of boiling water, salt and a tablespoonful of milk sugar. Let boil ten to fifteen minutes, remove from the fire. Add two to four ounces of hot cream. Flavor with vanilla, cinnamon, grated lemon rind or bitter almond.

MIXED FLOUR GRUEL. No. 2.

Put to boil the same amount of flour as in number one. Use a cup of rich milk and one and one-half of water instead of water alone. Flavor and serve.

ARROWROOT GRUEL.

Prepare the same as mixed flour gruel. Add hot cream.

NUT GRUEL. No. 1.

Mix two tablespoonsful of mixed flour with a little cold water, add two to three cups of boiling water, salt, and a teaspoonful of sugar, if desired. Boil 10 to 15 minutes. Stir a tablespoonful of almond-butter or combination nut-butter with one or two tablespoonsful of water to a smooth paste, add the gruel gradually, mix all well and serve.

NUT GRUEL. No. 2.

Heat a tablespoonful of butter in a flat saucepan, thicken with mixed flour, add two cups of boiling water, and salt, let boil a few minutes. Stir smooth a teaspoonful of almond-butter with cold water, add the gruel, mix well, flavor with lemon, if desired.

SAGO GRUEL.

Wash and soak a half cup of sago for several hours in a cup or more of cold water. Put into three cups of boiling water, add salt, a tablespoonful of milk sugar, or a teaspoonful of cane sugar, a stick of cinnamon, vanilla or lemon rind. Boil the sago 20 to 30 minutes. Remove from the fire, add three to six ounces of hot cream. Less sago may be used and a tablespoonful of rice flour dissolved with cold water added to it while boiling.

CORNSTARCH GRUEL.

Mix two tablespoonsful of cornstarch with a little cold water, add three cups of boiling water, salt, a tablespoonful of milk sugar or a teaspoonful of cane sugar, boil 10 to 15 minutes. Add two to three ounces of hot cream. One-half of rice flour and one-half of cornstarch may be used in place of pure cornstarch. Flavor as desired.

MILK GRUEL. No. 1.

Mix a tablespoonful of rice flour and one of cornstarch with a little cold water. Add one quart of boiling milk. Boil 10 to 20 minutes. Add salt and flavor, as desired.

MILK GRUEL. No. 2.

Bring one pint of milk and one pint of water to a boil. Dissolve two or three tablespoons of white flour with a little cold water and stir into the hot milk. Let boil 10 to 15 minutes. A stick of cinnamon, vanilla or lemon rind can be boiled with the milk. If the flavor of almonds is desired, grate one bitter-almond on it after it is removed from the fire. The yolk of an egg may be added, if desired.

PEPTONIZED GRUEL.

Prepare a gruel from any farinaceous article. Pour into a bowl and allow it to stand until lukewarm. Add peptonized powder according to direction.

CHAPTER XI.

FLUIDS.

STERILIZED MILK.

Put the desired amount of milk into clean sterilized bottles, put in cotton stopper, set on a grate and heat in a water bath to 170° F. or 212° F. Keep the milk at this temperature for 40 minutes or longer, then remove from the fire; when the water has cooled take out the bottles and place them on ice.

Recipes for the preparation of different forms of peptonized milk can be found in the directions given with digestive ferments, when bought at the drug store.

KUMYSS.

Dissolve one-fourth of a cake of compressed yeast in a little warm water. Take a quart of fresh blood-warm milk, add to it a tablespoonful of sugar and the yeast. Put the mixture into beer bottles with patent stoppers, filling them to the neck. Place them for about twelve hours in a room suitable for raising bread, at a temperature of about 70°, then put the bottles on ice, up side down, until wanted.

RICE WATER.

Wash one-half a cup of Carolina rice several times with water, then soak or put on to boil at once with three pints of water. Boil slowly for about an hour, strain, and sweeten, or flavor as desired. Serve plain or with one-fifth part of sterilized cream.

BARLEY WATER.

Prepare in the same manner as rice water.

EAGLE BRAND CONDENSED MILK.

It can be prepared in many different ways, and mixed with barley-water, and cream, or used for sweetening in the preparation of gruels.

TOAST WATER.

Toast a slice of stale wheat or black bread until thoroughly brown. Break into small pieces and pour on it two or three cups of boiling water. Cover tightly, and set aside for twenty minutes or longer. Strain, and flavor to suit the taste. Serve hot or cold.

TOAST AND APPLE WATER.

Prepare like toast water, and add the peelings of one or two apples before pouring on the boiling water.

LEMONADE.

Boil a quart of water for several minutes with three to five tablespoonsful of sugar, and the rind of one lemon. Remove from the fire, add the juice of two or three lemons or oranges, strain and cool. Fresh clean cold water may be added to suit the taste. This is excellent in fevers, where much fluid food is required. It may be served hot or cold.

BRAN TEA.

Soak over night a cupful of Ralston’s select bran in one quart of soft warm or cold water. The next day strain it and serve raw, or put it on to boil, simmer for one-half hour, then strain. Serve hot or cold. The bran may be mixed with oats or ryenuts when put to soak, and may be used raw or boiled. Hot bran tea with cream is excellent as a substitute for tea. It can be prepared without soaking.

BEEF JUICE. No. 1.

Broil one pound of thick round steak, cut into small pieces and press the juice out with a lemon squeezer or meat press. It may be served with or without lemon juice and be diluted with warm water, if desired. When heating, do not coagulate the albumen by boiling, but place the cup or bottle containing the juice in a kettle of warm water.

BEEF JUICE. No. 2.

Grind or chop some round steak, put into a quart jar and fill with warm water. Place the jar in warm water and let stand three or four hours. The temperature must not rise above 155° F. Strain through a cheese-cloth, and flavor with a little lemon or salt.

BEEF BROTH.

Wash a beef bone thoroughly with hot and cold water. Put on to boil and cook very slowly for three or four hours. It may be flavored with onion, potato or soup greens. Strain through a fine strainer or cheese-cloth. Serve hot or cold. If a few teaspoonsful of hot sterilized cream or the yolk of an egg is added before serving it will improve the taste and make it more nutritious.

JULIENNE BROTH.

Soak the desired amount of dried vegetable. Prepare as directed on package. Add some soup stock or beef extract before serving.

VEAL BROTH OR JELLY.

Take a bone of veal without meat, wash it thoroughly first with cold and then with warm water. Bring to a boil with cold water and pour off the first water. Bring to a boil again with hot or cold water, skim carefully, add salt, and let it simmer gently for several hours. Strain through a fine sieve or cheese-cloth. When cool set on ice. If thickening is desired, cook one-half a cup of Cook's flaked rice in an equal amount of water, and add a little salt. Mix with one-half a cup of veal jelly, and serve. A few tablespoons of cream may be added to it, or the broth may be served clear with zwieback.

BROTH WITH EGG.

Stir the yolk of an egg with two tablespoonsful of cold water until well mixed. Then gradually add eight to fifteen ounces of broth. Stir constantly to prevent the egg from curdling. If the whole egg is desired, beat it with an egg-beater and prepare in same way. Less than eight ounces of broth to one egg will make it too rich. A few drops of lemon may be added.

TOMATO AND VEAL JELLY.

Mix an equal amount of strained veal broth and strained tomato juice. Let cool and serve. If freshly strained canned tomatoes are used, do not cook the tomatoes. If it stands longer than twelve hours, bring to the boiling point in order to prevent fermentation.

VEAL JELLY.

Veal jelly may be flavored in many different ways. It is better to cook the stock with salt only. In this way the flavor can be changed each time by adding vegetable broth obtained by boiling vegetables in a small amount of water and straining. Onions are a very good flavoring. A great variety of vegetables should not be used at one time.

MALTED MILK. No. 1.

Put two teaspoonsful of malted milk into a cup, pour on some boiling water and add a pinch of salt and one-fourth of a cup of cream.

MALTED MILK. No. 2.

Prepare as the foregoing, omitting the cream. Serve plain, or add a few drops of lemon juice.

UNFERMENTED BEER.

Soak a cup of bran and a slice of thoroughly toasted black bread for several hours in a quart of water. Add a stick of cinnamon, bring to a boil and let simmer slowly for 20 minutes or longer. Strain and serve hot or cold.

CAMOMILE TEA.

Put a tablespoonful of tea into a teapot and pour on it one-half a pint of boiling water. Allow it to stand on a hot platter or over steam for 5 minutes. Then strain and serve.

FENNEL TEA.

Prepare the same as camomile tea.

BUCKTHORN TEA.

Put two tablespoonsful of buckthorn bark into a teapot, pour on it a cup of boiling water, and allow to steep from 10 to 15 minutes. Strain and serve warm (not hot).

WHEY. No. 1.

Soak one of Hansen's rennet tablets in a little cold water. Heat one quart of skim milk or fresh milk until it is lukewarm. Crush the tablet and mix with the milk, and stand on a warm place for 5 minutes or until it is thick. Then heat over the fire until the whey separates. Strain and throw away the curd.

WHEY. No. 2.

Heat some fresh milk until it is blood-warm. Add Fairchild's essence of pepsin, according to directions.

IRISH MOSS.

Wash and let it soak for several hours, or over night. Boil for 10 minutes, strain through cheese-cloth, and add one-half or two-thirds of a cup of hot milk. Flavor as desired.

RAW GREEN PEA JUICE.

Wash some fresh green peas in the pods and grind through a meat grinder, allowing the liquid to drain into a bowl.

LEMON WHEY.

Heat a pint of fresh milk to about 200° F., remove from the fire and squeeze into it the juice of one-half a lemon. Let stand for a few minutes, beat with a fork, and strain through a cheese-cloth. Serve hot or cold.

ALBUMEN WATER.

Add to the white of one fresh egg eight ounces of water and a little lemon juice or brandy, and shake thoroughly. Keep on ice.

FLAXSEED TEA.

Add a quart of water to two tablespoonsful of whole flax seed. Boil one or two hours with one or two tablespoonsful of sugar. Strain and add lemon juice or cream, to suit the taste.

APPLE BARLEY WATER.

Soak a cup of barley over night. Put to boil with two quarts of water, add a little salt and the skins of two or three apples, and a little sugar. Boil slowly for an hour or until it becomes red in color. Strain, and add lemon juice, if desired. Serve hot or cold.

WATER EGGNOG. No. 1.

Beat the whole of an egg with one-half a cup or less of water. Flavor with lemon juice.

WATER EGGNOG. No. 2.

Beat the yolk of an egg with one-half or a whole cup of water. Flavor with lemon juice.

LEMONADE WITH EGG.

Take some lemonade prepared from oranges and lemons and add to it the yolk or the whole of an egg. The acid taste must dominate the sweet taste.

MILK EGGNOG.

Beat up the whole or the yolk of an egg with a little water and some brandy, sherry, cognac or whiskey, and one or two teaspoonsful of sugar. To this add eight to ten ounces of rich raw or sterilized milk, or one-half cream and one-half water. Flavor with nutmeg or bitter almond.

FRUIT LEMONADE.

Boil some water with a little sugar and the rind of a lemon, orange or apple. Add to it some preserved strawberry, cherry, pineapple, currant or raspberry juice, and seltzer water, or add a mixture of several different fruit juices. This is excellent for fever patients, but not for people suffering with lung or heart diseases.

ALMOND MILK.

Blanch one cup of almond meats, chop or grind them coarsely, and pour over them a quart of hot water. Let stand several hours or over night, press through a cheese-cloth, and keep on ice. A few bitter almonds may be added.

BEER LEMONADE.

Wash a half cup of dried currants or raisins, put on to boil with a pint of water, a tablespoonful of rye nuts or black toast, a piece of cinnamon, some lemon rind and one or two tablespoonsful of sugar. Simmer slowly for fifteen minutes, add a pint of Munchener's Spatenbraü, let it boil for one minute, and strain. Keep in a cool place. Serve hot or cold.

STRAWBERRY MILK.

Wash two cups of fresh strawberries. Put into a milk-pitcher and add two quarts of fresh raw or cold boiled milk, a little vanilla and a small piece of ice. Strain, serve with zwieback or shredded wheat. Sugar may be added, if desired. This is more wholesome than ice cream.

EGG WINE.

Mix thoroughly the yolk of three eggs with three teaspoonsful of sugar. Add a pint of white or red wine or one-half of wine and one-half of water. Serve with zwieback or wafers.

TEA.

Rinse the teapot with boiling water. Take a teaspoonful of black Japan tea, add a pint of boiling water, and let stand over steam for one or two minutes. Strain, and serve hot or cold with lemon juice or cream.

COFFEE.

Grind very coarsely two tablespoonsful of fresh coffee beans. Pour two cups of boiling water on them, let stand 5 minutes (do not boil), then strain. Serve black or with cream. Tea and coffee should be used for medicinal purposes only.

MALT OR CEREAL COFFEE.

Take one-half cup of instantaneous Postum or Kneipp's malt coffee, pour three or four cups of boiling water on it. Let stand from 5 to 15 minutes, then strain. Serve hot or cold, with or without cream. People who wish to leave off coffee may add a teaspoonful of coffee beans to the cereal coffee a few minutes before straining. In this way they will gradually lose the desire for coffee. Bran tea or legume tea may be substituted for black tea or coffee.

COCOA. No. 1.

Dissolve one teaspoonful of cocoa and one of sugar in a little boiling water or milk and add a cup of rich milk. Let all boil a few minutes. Hot or whipped cream may be added before serving.

COCOA. No. 2.

Dissolve one-half a teaspoonful of cocoa and one teaspoonful of milk sugar in a little boiling water, add one cup of hot rich milk or one-half cup of cream and water, and boil a few minutes. Add more cream, if desired.

COCOA SHELLS.

Boil cocoa shells for twenty minutes, then strain. Use as a substitute for tea or coffee.

BEAN TEA.

Use white, brown or black beans; soak one-half cup of beans in warm soft water over night. The next day put on to boil in a quart of water, cook slowly for one hour or longer, and keep covered well. Then strain and serve plain, or add some hot cream to it. Small white and lima beans are excellent in the summer.

PEA AND LENTIL TEA.

Prepare the same as bean tea. Dry green peas are richer in minerals than yellow peas. Yellow peas contain more starch.

PART THREE

CHAPTER I.

FOOD REQUIREMENTS.

It is important that the diet should contain the proper amount of protein, starches and fats, suitable to the individual needs. Age, weight, size, occupation, season and climate must all be considered. The majority of civilized men and women consume from two to three times the amount of food necessary. Numerous and careful researches regarding food requirements have been made during the last fifty years.

The composition of American food materials and the dietary standards of Professors Voit and Atwater can be found on the last pages of this book.

The recent experiments of Professor Chittenden, of Yale University, have demonstrated that 60 grams of protein, with the necessary amount of fats and carbohydrates to yield from 1500 to 2500 calories per day, is sufficient. These requirements are regarded as presenting the minimum of what is necessary for the maintenance of health, strength and activity. To take more food than the body requires means not only waste of food, but an unnecessary strain upon the body, by this excess, which must be gotten rid of at the expense of energy, that could be more profitably expended for other purposes.

The sample menus given on following pages are taken from the results of my own experimental work with different people, under different conditions, and of weights varying from 130 to 160 pounds. They were people in poor health, suffering from lack of nutrition brought about by unsuitable food, such as too much protein or starchy foods; insufficient fats and minerals in the food; excess of cooked foods; improper combinations and wrong time for eating. Some improved in health and strength immediately after the change of diet, and were able to do from eight to twelve hours of active work, while others found it necessary to take a rest and develop their stomachs gradually by a change to raw foods.

I am convinced that the amount of protein presented in the sample bills of fare is sufficient for the average individual, provided the food is properly masticated, digested and assimilated, and not forced down by artificial stimulants and poisonous beverages. The amount of carbohydrates and fat required differs greatly with different temperaments and individual peculiarities, and must be determined by the individual himself. Those who can use a considerable amount of cereals and fruits require less fat, while others who are not so well able to digest large amounts of starchy foods and fruits require more fats.

Cooked foods are more easily digested than raw foods, but the nutritive value is very definitely influenced by the process of cooking; therefore it is important to consume as much food as possible in the raw state.

Sample of Daily Food Requirements (roughly described):

TABLE 1.

Grams _contain_ Protein Fats and Carbohydrates Milk 50 2 4 Rice, barley, noodles or corn 100 12 40 Lean meat 250 54 32 Greens 125 3 6 Bread 200 14 56 Butter 50 -- 34 Oil, ½■ cup (or fat meat) 150 -- 102 Fruit 300 -- 18 Eggs 100 12 16 -- ---- 97 308

TABLE 2.

Milk 50 2 4 Rice or any other cereal 100 12 40 Greens 125 3 6 Potatoes or carrots 100 2 11 Cheese (or nuts or legumes) 100 25 36 Oil, ½■ cup (or fat meat) 150 -- 102 Fruit 300 -- 18 Bread 300 21 84 Butter 50 -- 34 -- ---- 65 335

SAMPLE MENUS

I. BREAKFAST.

(Winter.)

Pearl barley with hot cream and French prunes. Two soda crackers.

Portion of food containing calories Pearl barley (measured raw) ½■ cup 450 Cream ½■ cup 230 French prunes 5½■ 100 Soda crackers 4 100 ---- 880

DINNER.

Tomato and lettuce salad with mayonnaise dressing. Baked beans with lemon and fat meat. Carrots.

Tomatoes 2 raw 100 Lettuce ½■ head 10 Oil 4 tablesps. 400 Egg 1 whole 60 Beans ½■ cup (raw) 300 Fat meat ½■ lb. 650 Carrots 1 large 50 Lemon Juice of ½■ 8 ---- 1578

SUPPER.

Tomato cream soup with toast and raw celery.

Butter 1 tablesp. 105 Strained tomato juice 1 cup 100 Cream ½■ cup 230 Toast 2 small slices 75 Celery 3 stalks (raw) 25 ---- 535

II. BREAKFAST.

(Summer.)

Strawberries, two boiled eggs with shredded wheat or toast, or raw wheat flakes.

Strawberries 1 cup 60 Eggs 2 120 Shredded wheat 2 200 Butter 1 tablesp. 105 ---- 485

DINNER.

Apple and celery salad with French or mayonnaise dressing. Boiled codfish with white sauce. Bread and butter. Black unsweetened coffee.

Apple 1 large 100 Celery 2 stalks 16 Oil 4 tablesps. 400 Egg 1 60 Lemon ½■ 8 Fish ½■ lb. 130 Butter 2 tablesps. 200 Flour 1 tablesp. 30 Black Bread 2 large slices 200 ---- 1144

SUPPER.

Muskmelon with lemon. Creamed chipped beef on toast.

Melon ½■ 60 Lemon Juice of ½■ 4 Chipped beef 3 slices 50 Cream ½■ cup 230 Toast 1 large 100 ---- 444

III. BREAKFAST.

(Summer.)

Banana, apple and lettuce salad with French or mayonnaise dressing. Stale black bread.

Apple 1 large 100 Lettuce ½■ head 10 Banana 1 100 Oil 2 tablesps. 200 Lemon Juice of ½■ 4 Black Bread 1 slice 100 ---- 514

DINNER.

Cream of wheat porridge with hot cream. Almonds and raisins.

Cream of wheat (raw) ½■ cup 250 Cream 3 ounces 273 Almonds 12 large 120 Raisins 12 large 100 ---- 743

SUPPER.

Strawberries with a large glass of raw mixed milk and cream and zwieback.

Strawberries 2 cups 120 Zwieback 2 100 Cream 4 ounces 230 Milk 8 ounces 165 ---- 615

IV. BREAKFAST.

(Summer or Winter.)

Steel cut oats or wheat with butter or hot cream. Two large carrots or cucumbers.

Oats (measured raw) ½■ cup 100 Butter 1 tablesp. 105 Carrots 2 large 100 ---- 305

LUNCH OR DINNER.

Sandwiches with butter and sliced American cheese or one-half blood or liver sausage and two apples.

Black or whole wheat bread 2 large slices 200 Butter 3 tablesps. 315 Cheese ½■ lb. 450 Apples 2 large 100 ---- 1065

SUPPER.

Green pea soup with fried bread and stewed prunes.

Peas (measured before soaking) ½■ cup 80 Onion 1 6 Bread 2 small slices 75 Fat for cooking and frying 4 tablesps. 400 Flour for cooking and frying 2 tablesps. 60 Prunes 6 120 ---- 741

V. BREAKFAST.

(Summer or Winter.)

Banana salad with lettuce and French dressing, grapenuts or ryenuts.

Banana 2 medium 200 Lettuce ½■ head 10 Olive Oil 2 tablesps. 200 Lemon Juice of ½■ 8 Grapenuts 1 tablesp. 30 ---- 448

DINNER.

Strained barley soup with prunes, beefsteak, sprouts and butter sauce, toast and black coffee.

Barley (before soaking) ½■ cup 450 Prunes 5 100 Butter 1 teasp. 105 Beefsteak ½■ lb. 160 Sprouts ⅜■ cup 30 Butter Sauce ½■ cup 135 Toast 1 large slice 100 Butter 1 teasp. 35 ---- 1115

SUPPER.

Baked apple with cream, puffed wheat or corn flakes mixed with pieces of butter, two soft boiled eggs, one-half cup of black coffee.

Apple 1 large 100 Cream ½■ cup 115 Puffed wheat ⅜■ cup 75 Butter 1 tablesp. 105 Eggs 2 120 ---- 515

FOOD FOR THE AGED

Many people at the ages of sixty and seventy still lead an active life, while others retire from activity at forty-five or fifty. Therefore, the food must conform to the person’s mental and physical requirements. If the teeth are poor and the digestive powers are weak, the food should be light, consisting mainly of well cooked cereals, baked potatoes, rice, cooked greens, a small amount of meat, raw fruits and raw greens in combination with fatty foods, as salads, milk and buttermilk, toasted breads and soups. The total fuel requirement depends upon whether the individual leads a quiet or active existence. For a person who lives mainly indoors, and makes little use of the muscles of the arms, shoulders and trunk, 1000 to 1200 calories is sufficient for twenty-four hours. If more food is eaten than the body requires, the excess will manifest itself by the development of chronic ailments and obesity, or feeble-mindedness.

The morning and evening meals should consist of fluid and semi-fluid foods, or of toasted breads and salads. Meats, eggs (except the yolks), cheese, beans, peas and nuts should be eaten only during the middle of the day in small quantities. One can cut down his amount of food greatly by thoroughly chewing each morsel. The demand for protein at this period is small, while the amount of fat should be increased. A few sample bills of fare may be of assistance to those who wish to make a study of food requirements for themselves or for others.

MENUS FOR THE AGED

I. BREAKFAST.

Apple salad with lettuce finely chopped, onion and mayonnaise dressing, bacon and crusts.

Portion of food containing calories Apple 1 medium 72 Lettuce ½■ head 5 Onion ½■ piece Oil 4 tablesps. 100 Lemon or vinegar About 2 teasps. 4 Yolk of egg 1 48 Bacon 2 ounces 325 Crusts 2 50 ---- 604

DINNER.

Clear soup with rice and egg. One lamb chop with sprouts, and one triscuit with butter.

Soup 1 cup 100 Rice (measured before soaking) 2 tablesps. 100 Yolk of Egg 1 48 Lamb chop 1 small 100 Sprouts ½■ cup 20 Butter sauce ½■ cup 135 Triscuit 1 35 Butter 1 teasp. 35 ---- 573

SUPPER.

One large glass of buttermilk, kumyss, peptonized hot milk or Dr. Metchinikoff's sour milk, with one slice of graham toast.

Milk 12 ounces 247 Graham toast 1 large slice 100 ---- 347

II. BREAKFAST.

Raw cranberries and celery with olive oil, one slice of graham or whole wheat toast with butter and unsweetened black malt coffee.

Cranberries ½■ cup 10 Olive oil 2 tablesps. 100 Toast 1 large slice 100 Butter 1 tablesp. 105 Raw Celery 2 stalks 16 ---- 331

DINNER.

Rice with cream or tomato sauce, eight almonds or one large zwieback with one level tablespoonful of almond butter and raisins.

Rice 3 tablesps. 150 Hot cream 2 ounces 115 Almonds 8 80 Raisins (large) 8 80 ---- 425

SUPPER.

Calves'-foot and tomato jelly with graham toast or puffed wheat and milk or black malt coffee.

Jelly ½■ cup 50 Puffed Wheat 1 cup 100 Milk 8 ounces 165 ---- 315

III. BREAKFAST.

Raspberries or strawberries, plain shredded wheat with cream.

Raspberries ½■ cup 30 Shredded wheat 1 100 Cream 2 ounces 115 ---- 245

DINNER.

Potato or apple salad, and lettuce with mayonnaise dressing, fish, black crusts and black coffee.

Potatoes 2 medium 150 Oil 4 tablesps. 400 Yolk of egg 1 48 Lemon or vinegar About 1 tablesp. 5 Raw onion (finely chopped) ½■ piece 3 Crusts 3 75 ---- 681

SUPPER.

Cook’s flaked rice gruel with hot cream, cream toast or vegetable cream soup.

Flaked rice 1 cup 100 Hot cream 2 ounces 115 Hot water 1 cup ---- 215

IV. BREAKFAST.

Cooked string beans with butter sauce and parsley, fried bacon and triscuit with butter.

String beans (cut up) ½■ cup 20 Butter sauce ½■ cup 135 Fried bacon 2 ounces 200 Triscuit 1 35 Butter 1 teasp. 35 ---- 425

DINNER.

Barley soup with crackers, pea puree on toast, stewed prunes with cream.

Barley 3 tablesps. 270 Butter 1 teasp. 35 Cracker 1 25 Pea puree 2 tablesps. 100 Toast 1 large 100 Prunes 5 100 Cream 2 ounces 115 ---- 745

SUPPER.

Bran tea with cream. A piece of cake or a slice of light egg toast.

Bran ½■ cup 110 Cream 1 ounce 58 Egg 1 60 Soupstock ½■ cup 25 Butter for frying 1 tablesp. 105 ---- 358

CHAPTER II.

DIET DURING PREGNANCY.

A healthy woman will be guided by intuition as to the selection of food suited to her condition. Unfortunately, only a few women are properly matured in these days of forced education and unnatural occupations for young girls during the age of puberty.

The craving of pregnant women for pickles, spices and certain fruits out of season indicates an anemic condition. The individual longs for an article, of which her mind is most conscious, to bring about satisfaction.

Pregnant women require a larger amount of phosphates, lime and other minerals in their food, especially during the first four months. The amount of food taken should be rather less in quantity; and the starches and sweets should be cut down as much as possible, unless the mother has to perform a large amount of physical work.

Vomiting during the early months of pregnancy is generally due to excess of starches and indigestible foodstuffs. The eliminating organs not being able to throw off the excess of waste, the system rids itself of it through the effort of the liver, before the waste enters the blood stream.

A suitable diet depends much upon the constitution of the mother. In severe cases of vomiting or headache, a diet should be prescribed by a physician.

DIET FOR THE MOTHER AFTER LABOR.

This is another important period for the welfare of the mother as well as of the infant. Improper feeding during the first month after the child is born is responsible for many nervous breakdowns of the mother, at the time when she should be in the best of health and ready to take charge of her infant. A healthy new born infant can stand an enormous amount of abuse in the matter of feeding before it is sent to an early grave, or before the foundation is laid for a life of long suffering.

The mother’s milk during the first month of the infant’s life is richer in cream and sugar than in the later months. Therefore, such foods should be given as yield these elements to the milk. The mother herself, having expended a large amount of energy, demands a food rich in lime, fats, sugar and organic salts. The physiological enlargement of the abdominal organs must be treated with great care.

As a rule, no food is required during the first few hours except water. In exceptional cases where the mother is greatly exhausted, a glass of fresh milk or some warm stimulating food may be served.

The food during the first four days should consist largely of strained water gruels, prepared from steel cut oats and bran, or from rolled wheat or cream of wheat. Stewed prunes, toast, soft boiled eggs or other egg foods should be served once per day at the noon meal. Fresh milk is best given during the afternoon or evening or at 10 a. m. A slice of toast may be served with it. If the milk of the mother is scanty, serve water gruels several times per day. If the mother has too much milk, fluid foods should be restricted and a dry diet adopted. After the fourth day add rice, baked potatoes, fish and a small amount of meat to the diet. Avoid drinking milk or other liquid food, except a little water with the dinner. If milk or broth is desired, take it at the beginning of the meal. Avoid artificially prepared desserts at the end of the meal. Use oranges or grapes as desserts, or a little black coffee and toast.

Suggestive Menus for Breakfast during the First Week.

1. Three-fourths of a pint of barley gruel with or without cream, 2 crusts.

2. Eight ounces of cornmeal mush with egg and dried fruit. 4 ounces of hot cream. 2 crusts.

3. Stewed or soaked French prunes with whole wheat bread and butter. 10 ounces of bran tea or Kneipp’s malt coffee with cream and milk-sugar.

4. One pint of bran and oatmeal gruel with butter, soaked French prunes, 2 black crusts.

5. Eight ounces of fresh raw or boiled milk with 3 ounces of barley water and a slice of toast.

6. Rice flour with egg and currants and hot cream and 2 crusts.

7. Rylax with hot cream, soaked prunes or raisins.

8. Bread soup with hot cream, soaked prunes or raisins.

9. Rice with hot cream and soaked prunes or raisins.

10. Malt coffee with toast and butter. Soft boiled eggs.

Menus for Dinner during the First Week.

1. Cream toast, light rice, or cornmeal with egg.

2. Soup of asparagus or green peas with toast.

3. Soft boiled eggs with toast, baked apple.

4. Cream of bean or lentil soup, bread and butter.

5. Broth with egg. Fish with baked potatoes, apple sauce with toast and butter.

6. Spinach with boiled eggs and bacon. Bread and butter.

7. Barley soup with crackers. Lamb chop with sprouts and yolk of one egg.

8. Chicken soup with rice. Chicken with string beans, stewed prunes.

Menus for Supper during the First Week.

1. Strained barley or oatmeal gruel with cream.

2. Cream of wheat or farina with cream.

3. Sago or tapioca with cream and zwieback.

4. Malt coffee or bran tea with cream and zwieback.

5. Boiled custard with fruit sauce and zwieback.

6. Cream of pea or lentil soup with celery.

7. Cream toast or shredded wheat with cream.

8. Cream of tomato soup with zwieback and celery.

If food is required between meals, give plain milk, bran tea, or malt coffee with cream and zwieback.

CHAPTER III.

CARE AND FEEDING OF CHILDREN.

THE NURSERY.

The nursery should be well lighted and ventilated, and if possible be located on the southeast side of the house. The windows should be broad and not too low. The wall-paper should be a cheerful green or blue with designs of lighter shades, and the rug of brown or tan color. Avoid all bric-a-brac, useless curtains, and other hangings which tend to darken the room, gather dust and absorb odors. The furniture should be adapted to the size and needs of the child. During the first four years the meals are best served in the nursery, or at a time when the parents are not at the table. It avoids much unnecessary excitement and temptation, and if the child is under the constant care of the mother it will give her relief during these hours. All children between the ages of four and ten should have their evening meals served alone, or else be so well trained as not to expect to eat the same food as the adults.

PREPARATION OF FOOD FOR INFANTS.

MILK.

In preparing modified milk or other fluid foods for infants, where top milk is used, it is very important that the milk contain the same amount of cream for each feeding, or else digestive disturbance and irregularity of bowel movements will occur.

If milk, fresh from the cow and run through the cooler, is put into bottles or jars and kept at the same temperature, the same percentage of top-milk will be obtained daily. Five hours is generally sufficient to obtain the desired quality. The best means of removing it is by a spoon or siphon.

If raw milk is used without being sterilized, the desired amount for each meal should be put into sterile bottles directly after delivery and lightly covered by cheese-cloth or cotton and kept on ice or other cold place. In this way each bottle will contain the same amount of cream.

PREPARATION OF MODIFIED MILK (RAW).

Put the desired amount of top-milk into as many bottles as are required for feeding during twelve hours. Prepare a solution of water and milk-sugar by dissolving the sugar with the desired amount of boiling water. Let cool and keep on ice for twenty-four hours. At each feeding, add the prescribed amount of water to the milk, shake and heat in a water bath. Add a tablespoonful of lime water or barley water. If the milk cannot be obtained fresh twice per day, it is safer to scald the milk which is used during the night.

All milk, even if handled carefully, contains a large number of germs. When one is not certain that the cows from which the milk is obtained are healthy, the milk should be sterilized. During the summer it is safer to scald or sterilize all milk for infants.

SCALDED MILK (MODIFIED).

Dissolve the desired amount of milk sugar in boiling water in a clean saucepan, add the milk, stir over a quick fire until it foams, which means that the milk is heated to about 200° F. The most harmful germs are generally destroyed by this process. Pour the milk into a clean pitcher and set the latter in a pan of cold water. Stir the milk until cold and change the water several times. The stirring makes the milk homogeneous and easier to digest. If any scum has formed on top, through careless preparation, the milk should be strained through a cheese-cloth before putting it into bottles. Put a cotton stopper in the bottles and set on ice. Milk prepared in this manner is generally suitable for the average healthy infant.

STERILIZED MILK (MODIFIED).

Dissolve the milk sugar as directed for scalding milk. Add the desired amount of milk, top-milk or cream, and prepare as directed in the chapter under “Sterilized Milk.”

PASTEURIZED MILK.

Put the desired amount of milk or milk and cream mixture into sterile bottles, put on a stopper and set in a water bath; heat the water to 155° or 170° F., and keep it at that temperature for 30 minutes. Then remove the bottles at once, cool them in a pan of cold water and set on ice.

BOILED MILK.

Put the desired amount of milk, or modified milk, into a clean saucepan, stir over a hot fire and boil from 2 to 5 minutes. Then cool by setting the pitcher into a pan of cold water; stir until cold and set on ice. This is excellent for infants as well as for the sick who suffer with diarrhœa. The milk may be modified with arrow-root, barley water or rice flour gruel, which has been boiled with salt and water and a stick of cinnamon. Milk-sugar should be boiled with the gruels, two level tablespoonsful to a pint of boiling water.

ESKAY’S FOOD.

Prepare as directed on label or use like the foregoing in place of arrow-root.

DR. BIEDERT’S MILK AND CREAM MIXTURES.

1st month--4 ounces of cream, no milk, 12 ounces of water, 3 tablespoonsful of milk-sugar.

2nd month--4 ounces of cream, 2 ounces of milk, 12 ounces of water, 3 tablespoonsful of milk-sugar.

3rd month--4 ounces of cream, 4 ounces of milk, 12 ounces of water, 3 tablespoonsful of milk-sugar.

4th month--4 ounces of cream, 8 ounces of milk, 12 ounces of water, 3 tablespoonsful of milk-sugar.

5th month--4 ounces of cream, 12 ounces of milk, 12 ounces of water, 3 tablespoonsful of milk-sugar.

6th month--no cream, 16 ounces of milk, 8 ounces of water, 2 tablespoonsful of milk-sugar.

DIRECTION FOR PREPARATION.

Put the desired amount into a saucepan and scald, as directed under “Scalding Milk,” or put into bottles and pasteurize or sterilize.

If the bowels of an infant are too loose, lessen the amount of cream, and add more milk in place of it. If the child is constipated, add more cream and use less milk. If it disagrees, add oatmeal, rice, rye, barley or legume water. For preparation, see “Teas,” in Chapter on Fluids. Use one-half the amount of water, as directed above, add the other half in the form of tea. Prepare the tea separately, and add the desired amount to each bottle when heating. Camomile tea is often beneficial for a few days. It can be added in the same manner as other teas, or given without sugar or cream, when colic appears. The latter way is preferable to too much hot water, when the infant is suffering with colic.

ORIGINAL RECIPE FOR DELICATE INFANTS.

=Mixture of Cream, Milk, Water, Milk-Sugar, Rice Flour and Pearl Barley--(Condensed Milk, if Required).=

Dissolve two tablespoonsful of rice flour in a little cold water, stir into twelve ounces of boiling water, add one-fourth of a teaspoonful of salt, and boil for 20 minutes. Pour into a pitcher and keep on ice for 24 hours. Use.

Soak one-fourth of a cup of pearl barley for several hours, or over night. Boil with a quart of water and a little salt for one and one-half hours. This will make about ten ounces of barley water when strained. Keep the barley water and rice flour gruel in separate pitchers. If an additional amount of condensed milk is found more agreeable, add one tablespoonful of Eagle Brand Condensed Milk to the barley water in place of milk-sugar, before straining it.

Prepare the milk as follows: Dissolve two tablespoonsful of milk-sugar in ten ounces of boiling water, add four ounces of cream and four of milk, stir the milk and water in a saucepan over a quick fire until it foams, and pour into eight clean warm bottles which have been set in a kettle of hot water. Put cotton stoppers in the bottles, and pour enough water into the kettle so that it is even with the

milk in the bottles. Let it stand on a hot stove and keep the water at the temperature of 170° to 200° F. for half an hour. Then set the kettle on the floor and when the water is cold, remove the bottles and put them on ice. At each feeding, add one ounce of the prepared barley water, and a tablespoonful of rice flour gruel to the bottle; shake well, and heat by setting the bottle in warm water. This will make about 28 ounces of food for 24 hours, or 3½■ ounces per bottle for eight feedings during 24 hours. This quantity is required for the average child during the second month. Ten feedings are generally required during the first month.

During the first week of the infant's life use 5 ounces of cream, 5 ounces of water, 8 ounces of rice and barley water, and no milk. This makes 18 ounces of food for 24 hours, or about 2½■ ounces per bottle for ten feedings during 24 hours. If a larger quantity is desired during the first month, add 2½■ ounces of water and 2 ounces of milk to the cream mixture, then gradually change to the proportion given in above formulas. As the child grows older, increase the amount of milk to 12 or 15 ounces until the age of ten months. After that age 42 ounces of food is required during 24 hours, and the child is generally able to begin with semi-liquid or solid food. The rice flour alone, or any other cereal gruel or water may be used in place of barley and rice, but the latter is found especially beneficial for delicate infants with whom plain modified milk disagrees.

It is often desirable to change the cereal occasionally. Use oats, rye and barley during the winter and the lighter cereals during the summer. Other suitable foods for the infant are bran or rye tea with or without milk or cream, and broths from veal or mutton with the yolk of an egg (10 ounces of broth to one yolk). Strained steel cut oats and bran are excellent for a while where milk or cream are found to disagree.

During the period from the tenth to the fifteenth month the healthy infant requires an addition of solid food. The appearance of the teeth indicate when it should begin. The change must be made gradually from liquid to semi-liquid and finally to solid food. The middle of the day is the best time to begin with the change of food. Lean meat is not a necessary food for children, therefore it is mentioned only occasionally for those who think their children must have it. On, the other hand, legumes are a very important food for young children, and their use should begin during the second year. They are easily digested if prepared in the form of soups and purees, and combined as directed in the different menus. They should not be given at night.

SECOND PERIOD: FROM THE TENTH TO THE FIFTEENTH MONTH.

During this period the infant should sleep three times during the day: From 8 to 10 a. m., from 1 to 3 p. m., and from 6 to 8 p. m. If the child should not awaken for the last feeding and sleep until 4 or 5 a. m., give the feeding at 4 a. m. instead of between 8 and 10 p. m. If it should be in the habit of awakening during the middle of the night, change the habit by awakening it at 10 p. m. Reduce the quantity of milk given at this time gradually to 3 or 4 ounces, and finally replace it by water.

If the child should sleep from 6 p. m. to 6 a. m. without awakening, it does not require the extra feeding; four meals are sufficient.

Some children require five meals until they are two years old. With intelligent study and simple regularity the mother can make her work very easy. She can transform delicate children into strong, vigorous ones, avoid disease and many unnecessary doctor bills.

Do not begin the habit of stuffing the child with bread and crackers every time it cries. If it desires something to bite upon give it a teething-ring. Give the child as many meals as it requires, but avoid feeding between meals. Give it cold or slightly warmed water between meals. Do not force the child to drink water. If fed correctly it will call for the necessary amount of water. If a child is too heavy in weight for its age, reduce the amount of milk. Give it strained oatmeal, bran and barley gruels, with butter or cream. Some children require three pints of milk during 24 hours, between the tenth and fifteenth months, while others are satisfied with one and one-half pints of milk and four to six ounces of cream. If broths or other nutritious liquids are substituted for milk, the amount of milk required for the day would be less than that mentioned above. Never force the child to eat food; when it awakens in the morning it generally requires food immediately. When it awakens for its dinner, let it play for a while until it calls for food. If it refuses food, leave out a meal once in a while, or reduce the number of meals to suit the appetite.

MENUS FOR THE SECOND PERIOD: FROM THE TENTH TO THE FIFTEENTH MONTH.

I.

Between 6 and 8 a. m.--Plain or diluted milk.

Between 10 and 12 a. m.--Flaked rice gruel with sterilized cream.

Between 2 and 3 p. m.--Ten to twelve ounces of plain or diluted milk.

Between 5 and 6 p. m.--One cup of broth with egg, one-half slice of toast with butter.

Between 8 and 10 p. m.--Ten to twelve ounces of plain or diluted milk.

II.

Between 6 and 8 a. m.--Gruel of steel cut oats with one-half part of sterilized cream.

Between 10 and 12 a. m.--Bread gruel with butter or cream.

Between 2 and 3 p. m.--Ten to twelve ounces of plain or diluted milk.

Between 5 and 6 p. m.--Sago gruel with zwieback and butter (prepared with unfermented beer).

Between 8 and 10 p. m.--Ten to twelve ounces of plain or diluted milk.

III.

Between 6 and 8 a. m.--Strained barley gruel with sterilized milk.

Between 10 and 12 a. m.--Prune toast with beachnut bacon. Between 2 and 3 p. m.--Plain or diluted milk.

Between 5 and 6 p. m.--Sago gruel with cream and crackers or zwieback.

Between 8 and 10 p. m.--Plain or diluted milk.

ADDITIONAL MENUS SUITABLE BETWEEN 10 AND 12 A. M.

1. Cream toast. 2. Barley and bread gruel. 3. Bran and oatmeal gruel. 4. Cream of tomato soup with crackers. 5. Toast with creamed chipped beef. 6. Baked oats with prune jam and beachnut bacon. 7. Baked cornmeal with egg and cranberry sauce. 8. Light egg toast. 9. Soft boiled egg and toast.

MENUS FOR THE THIRD PERIOD: FROM THE FIFTEENTH TO THE TWENTY-FOURTH MONTH.

I.

Between 7 and 8 a. m.--Strained steel cut oats with sterilized cream.

Between 11 and 12 a. m.--Ten to twelve ounces of plain or diluted milk.

Between 1:30 and 2:3O p. m.--Light rice with sterilized cream and crackers.

Between 5 and 6 p. m.--A cup of unfermented beer and toast with butter.

Between 8 and 9 p. m.--Ten to twelve ounces of plain or sterilized milk.

II.

Between 7 and 8 a. m.--Cream of wheat with sterilized cream.

Between 11 and 12 a. m.--Broth with egg, and toast with butter.

Between 1:30 and 2:30 p. m.--Juice of one-half an orange, black bread pudding, celery.

Between 5 and 6 p. m.--A cup of plain milk and two graham crackers.

Between 8 and 9 p. m.--Ten to twelve ounces of milk, plain or diluted, with rice or barley water.

III.

Between 7 and 8 a. m.--Cornmeal mush with cream.

Between 11 and 12 a. m.--A cup of unfermented beer with zwieback and butter.

Between 1:30 and 2:30 p. m.--Three to five strawberries, one to one and one-half egg with toast and cereal.

Between 5 and 6 p. m.--A cup of plain milk with zwieback and calves' foot jelly.

Between 8 and 9 p. m.--Ten to twelve ounces of milk.

IV.

Between 7 and 8 a. m.--Bread soup with cream or butter.

Between 11 and 12 a. m.--Plain milk with unsweetened graham crackers.

Between 1:30 and 2:30 p. m.--Strained bean soup with buttered toast.

Between 5 and 6 p. m.--A cup of milk with crackers, or cream of tomato soup.

Between 8 and 9 p. m.--Plain or diluted milk per bottle.

V.

Between 7 and 8 a. m.--Rylax with sterilized cream.

Between 10 and 12 a. m.--Plain milk and crackers.

Between 1:30 and 2:30 p. m.--One-third to one-half cup of raspberries, eggs with toast and butter.

Between 5 and 6 p. m.--Plain milk and crackers.

Between 8 and 9 p. m.--Plain or diluted milk.

VI.

Between 7 and 8 a. m.--Turoena with cream and black crusts.

Between 10 and 12 a. m.--Plain milk and crackers.

Between 1:30 and 2:30 p. m.--Pea puree on toast, celery.

Between 5 and 6 p. m.--Plain milk and crackers, or tomato soup with cream.

Between 8 and 9 p. m.--Plain or diluted milk.

VII.

Between 7 and 8 a. m.--Black cream toast or shredded wheat with cream. Between 10 and 12 a. m.--Plain milk or broth and crackers.

Bet'n 1:30 and 2:30 p. m.--Light rice pudding, three ounces of strained tomato juice.

Between 5 and 6 p. m.--Unfermented beer, stale bread and butter.

Between 8 and 9 p. m.--Plain or diluted milk.

VIII.

Between 7 and 8 a. m.--Rice with sterilized cream or butter and egg.

Between 10 and 12 a. m.--Plain milk with crackers.

Bet'n 1:30 and 2:30 p. m.--Two leaves of lettuce, one carrot, one tablespoon of bean puree on toast.

Between 5 and 6 p. m.--Cream of tomato soup with zwieback.

Between 8 and 9 p. m.--Plain or diluted milk.

ADDITIONAL MENUS FOR DINNER DURING OR AFTER THE THIRD PERIOD:

1. One-half orange, one or two ounces of boiled fish, one-half of an apple, one to two tablespoons of raw rylax.

2. One-half of an apple, one or two eggs, one to two tablespoons of raw rylax.

3. Cereal salad with carrots and fish.

4. Legume soup, butter and bread, raw carrots.

5. Well boiled macaroni, one to two tablespoons of cold grated cheese.

6. Light rice with cold grated Swiss cheese.

7. Cereal salad with apple and eggs.

8. Lettuce, baked potatoes, beachnut bacon and one egg.

9. Mashed carrots, two tablespoons of young green peas, bacon, toast with butter.

10. String beans with stale bread and butter, bacon and egg.

11. Finely chopped spinach, bacon, egg, stale bread, butter.

12. Three to five cherries, light omelet.

13. Cereal salad with chopped apples, two to three tablespoons of cottage cheese.

14. Baked oats with prunes or cranberry sauce and bacon.

15. Whole wheat with sterilized cream and celery.

16. Peach and cereal salad, beachnut bacon and one egg.

ADDITIONAL MENUS FOR SUPPER DURING OR AFTER THE THIRD PERIOD.

1. Rice with egg and clear soup.

2. Gruels prepared with milk, cream, bran, bread, egg or soup stock.

3. Plain milk with stale bread or zwieback.

4. Huckleberry or cherry soup with whites of egg, and zwieback with butter.

5. Cream of tomato or thin pea soup with celery or zwieback.

6. Vegetable soups of asparagus or of strained canned corn.

7. Rice flour with egg, currants and cream.

8. Chocolate cornstarch with cream and black crusts.

9. Apple-sago or cornstarch with egg and cream, and zwieback.

10. Calves’ foot jelly with tomato, zwieback with milk.

11. Cook’s flaked rice gruel with cream and cracker.

12. Boiled custard with fruit sauce and black crusts.

13. Potato soup with cream and black crusts.

14. Clam broth with cream and zwieback, or with Grant’s crackers.

15. Melon with lemon, finely chopped chipped beef on toast.

16. Poached eggs on toast.

17. Fruit or vegetable soups with cream or egg.

18. Milk soups or milk gruels with black crusts.

19. Beer soups with egg or cream and zwieback.

20. Fruit toast with rich milk.

21. Broth with egg triscuit or zwieback with butter.

22. Red fruit pudding with cream and zwieback.

23. Baked apples in gelatine with cream and zwieback, or with Grant's crackers.

24. Thin legume soups with cream or butter.

Some children are able to digest all the above mentioned foods before they are three years old; others are not. Certain foods are agreeable to certain temperaments and disagreeable to others. No exact rules can be laid down. Reason and judgment must guide the mother in the selection of foods as well as in other details.

GENERAL SUGGESTIONS.

Unleavened crackers, raw cereal flakes and stale sundried pompernickle or whole wheat bread are the best dry cereal foods for children. If cooked cereals are served, crackers and wheat bread are not necessary at the same meal. A few black crusts or raw vegetables combine better with cooked cereals.

Soda crackers or thoroughly toasted unsweetened zwieback may be given occasionally for the evening meal in combination with sago, fruit gruels or jellies.

Do not feed a child fresh breads and cakes which contain soda, yeast or baking powder.

A child over three years of age may eat occasionally unleavened fruit cake, pancakes and fruit tarts which are prepared with eggs.

Never allow a child to eat ice-cream at the end of a heavy meal. Serve it at the beginning of the meal or during the afternoon.

Four meals per day is generally the best plan for a child, as long as it sleeps during the day-time. If it is fed on plain, non-stimulating food it generally takes a nap up to the age of 4 or 5 years, and sometimes later, while a child that is fed upon meats, beef juices, meat soups and excess of starch and sweets often refuses to sleep during the day-time at the age of two.

Meats and sweets or excess of any kind of food irritate the sensitive nerves and produce restlessness and sleeplessness in the child, and much unnecessary work and sleepless nights of the mother. Any normal healthy child can be trained in the matter of eating, sleeping, evacuation of the bowels and in other details like clock-work, if the proper conditions are furnished.

At the end of the third year the child may begin to eat well baked beans, peas or lentils several times per week during the winter. They should be given at the noon meal, in combination with raw or finely mashed carrots, or with a tomato salad and raw greens. No more than two tablespoonsful should be given at one meal. Systematic training in chewing is absolutely necessary for a good digestion. If legume foods should cause gas on the stomach, they must be strained and given in the form of soups or purees. Walnuts may also be used. Give two or three at the end of the meal. For combination, see "Menus for Adults." The amount of food should be increased gradually. At the age of 12 or 14, a child may eat nearly as much as an adult.

Moving picture shows, car and automobile rides require more nervous energy than strolling in the woods. Instead of supplying the system with plain nutritious foods, such as milk, nut preparations or wholesome sandwiches on such occasions, the excitable nerves are generally more stimulated by artificial foods: candies, cookies, sweet graham crackers, gums or by exhilarating (pure fruit?) lemonade or germ laden ice-cream.

Artificial lights and amusements of this kind, associated with nerve starvation, cause much eye trouble in children. Think of the amount of nervous and muscular energy expended during those hours in comparison with walks or other kind of natural amusements!

If the chewing of gum, candies and other fancies is permissible in cars and theatres, why not wholesome foods? A small satchel will hold an aluminum can with milk, a few napkins and other wholesome food products. If confectionery and ice-cream parlors and cheap restaurants were supplanted by hygienic food laboratories and pure water stands, saloons would soon be on the decrease.

WRONG MANAGEMENT.

The dyspeptic business men and women who have no time or power to digest a meal during the middle of the day are generally the victims of early habits acquired when at school.

We cannot try to change the fixed and immovable laws of nature without paying the penalty. Nature will keep us in order and control our machine, if we fulfill her laws. The sun is in sympathy with our digestive forces; therefore we should rest from labor during the middle of the day, so that the muscles of the stomach may be able to give all the circular movements, and others that are necessary, to thoroughly mix the food with the stomach juices for rapid digestion. Solid foods of the protein class, can only undergo perfect digestion if eaten in the middle of the day. They require many hours to digest, and in this way they are ready for oxidation and assimilation at night, when the air is cool. The body can rest, and the lungs and heart can work better when the stomach is emptied. While on the other hand, if the heaviest meal is taken at night, it is either too rapidly digested by physical force, or it is left half digested in the stomach over night. It congests the liver and kidneys, produces fermentation, robs lungs, heart and skin of their nerve force, and creates an abnormal appetite the next morning for an excess of energy-giving food, or it produces a languid feeling and loss of appetite. Such a system of living is responsible for the large number of acute and chronic diseases and consumption, while those who seemingly keep in good health under such conditions do surely shorten their life.

Perfect health and comfort are worth more than earthly possessions, and those who strive earnestly to possess and retain health will find a way to change their system of living. There is strength in union, and if a sufficient number of sensible people demanded different hours for school-children and for people who work indoors, it would be possible to obtain them.

During hot summer days or in the tropics the noon hour is not always the best for the heaviest meal of the day, but neither should it be spent for work. Two meals per day is the best plan on hot days. An individual who is always keyed up to the highest point during the middle of the day, and expends the best of his energy for work, cannot expect anything else but bankruptcy.

For people who desire two meals per day, the best time for breakfast is between nine and ten in the morning, and for dinner between three and four in the afternoon.

If three meals are taken, hard muscular workers, or those who are employed out of doors, do well to substitute for their dinner a substantial cold or warm lunch. If through lack of time and convenience a child cannot have its dinner before 4 p. m., it is better off without it. Remember that a cooked dinner consisting of meat, potatoes and vegetables is not at all necessary for the child’s welfare and development, and cooked vegetables should never be forced upon it if it prefers to eat them raw. Healthy children have keen instinct, and unless their appetite has become perverted by sweets and other artificial, unnatural foods, they are more likely to select the right kind of food than the average adult.

This book gives a large number of menus, consisting of raw foods, which can be quickly prepared when the child comes home from school. Nuts, fruits and raw vegetables form an ideal diet for the summer. Baked beans, peas and lentils warmed over, or jellied fish, egg foods, cheese or steamed puddings in combination with a warm soup or raw apples form a perfect meal during cold, winter days. If the dinner is eaten between the hours of 3:30 p. m. and 4:00 p. m., no more food is necessary. If it is served at noon, give milk or soup between 5 and 6 p. m. Children should take at least one-half an hour’s rest before eating, when coming home from school. The better way would be to allow children two hours for their noon meal or curtail the hours of school work from 9 a. m. to 1 or 2 p. m. Such is the custom in many European countries, and there is no reason why it could not be practiced here.

Children between the ages of eight and fourteen should retire between 7 and 8 p. m. If they get sufficient sleep and are properly fed, children’s diseases need not be feared.

CHAPTER IV.

LIGHT LUNCHES AND SANDWICHES.

LIGHT LUNCHES.

Menus for children, students at college and men and women who have to toil indoors. They can be had in almost any good cafeteria, or be prepared quickly on a gas or alcohol stove:

1. Corn and tomato soup with black crusts.

2. Cream of tomato soup with zwieback.

3. Green pea soup with zwieback and celery.

4. Broth with egg. Sandwiches with bologna or cold meat.

5. Buttermilk with graham toast.

6. Fresh milk with tomato toast.

7. Fruit gruel with white of eggs, and bread or toast with butter.

8. Strained canned tomato juice with whole wheat toast and butter.

9. Orange juice, green leaf vegetable with fried bacon and soft boiled eggs.

10. Pineapple salad with whipped cream and toast.

11. Apple or banana salad with lettuce and French or mayonnaise dressing, orange juice.

12. Potato salad with lettuce and soft boiled eggs.

13. Strawberries, raspberries or blackberries with rich fresh milk and zwieback or toast, butter and eggs.

14. Cherries and egg food.

15. Cream cheese with apples and sandwiches.

16. Fig or date butter with ryenuts and rich fresh milk or sandwiches.

17. Raw huckleberries (one-half to one cupful) with butter and stale bread.

18. Lettuce with two or three bananas and one-half to one glass of strained cranberry juice.

19. Apple salad with lettuce and almond cream or whole almonds.

20. Apples, raisins and six to twelve nuts.

21. Gelatine of fruit, or bread and bran with cream and toast.

22. Clam broth or cream soup with toast and raw celery.

23. Musk melon with lemon and berries.

24. Baked apples in gelatine with fish salad.

25. Ambrosia or apple sauce with whites of eggs and toast.

LUNCHES FOR THEATRES.

Cocoanut wafers, macaroons prepared with almond paste, Hershy’s chocolate, white figs and rye nuts, sandwiches with fruit butter or ground dried fruits and nuts.

AFTERNOON DRINKS AND DAINTIES.

Postum, weak tea, bran tea with cream, unfermented apple juice, fresh apple cider.

FOODS--Fruit cakes, tarts, cream puffs, cream rolls, zwieback, Huntly and Palmer biscuits, nabiscos, sandtarts, ice-creams, fruit gelatines.

SANDWICHES.

The sandwich is an important part of the bill of fare. It is not necessary to eat a cooked dinner in order to have a square meal, but for those who work indoors and are unable to take walking exercises before or after their noon meal, it is important to take some warm fluid or semi-fluid food in the form of broth, milk or soup as an entree or with their meal. With the convenience of modern inventions of gas, alcohol and electric stoves, or patented bottles which keep food warm for hours, this is easily obtained.

An endless variety of nutritious lunches can be prepared from left-over or fresh vegetables, meats, fish, eggs and cheese, or from raw cereals, nuts, fruits and greens. The bread used for sandwiches should always be stale or sun dried and be kept in a dry place in a tin box with good ventilation.

MENUS FOR LUNCH OR SUBSTITUTES FOR DINNER.

Grated Cheese with Apples and Buttered Bread.

1. Grate two to four ounces of Swiss or American cheese and carry in a glass jar or paper bag. At lunch-time peel one or two apples, cut them up in small pieces and mix with grated cheese. Eat with buttered bread.

Meat Sandwiches with Olives and Mayonnaise Dressing.

2. Prepare a salad from left-over meat, mixing with olives and dressing, or slice the meat and put between layers of bread, and mix the olives with mayonnaise dressing.

Scrambled Eggs on Sandwiches, and Cherries.

3. Eat the cherries at the beginning or at the end of the meal; lettuce is a good addition.

Ground Nuts with Apples and Raisins.

4. Grind six to twelve nuts in the morning and keep in a jar or paper bag. At lunch-time cut one apple into small pieces, add twelve raisins and the ground nuts. Eat with or without bread and butter. It is best to use only one kind of nuts at a time. Celery is also a good addition.

Nut and Date Sandwiches.

5. Remove the stones from one-half dozen or more dates, cut the dates into small pieces and mix with one-third or one-half the amount of chopped or ground walnuts. Spread on buttered bread or eat the bread with it. Apples combine well with it, either as a substitute for bread or in combination with it. In place of whole nuts, nut-butter may be used; the latter should always be diluted with an equal amount of water.

Figs, raisins or dried currants can be used in the same way as dates. Lettuce and celery are good additions.

Tomatoes with Popcorn, Bread and Butter.

6. Prepare a salad with tomato and lettuce, or strain some canned tomatoes. The latter can be carried conveniently in a small Mason jar. Always open the jar a little, if left to stand in a store or office, so the air can circulate through it. Take one cup of tomato juice in combination with one-half pint or more of warm, buttered popcorn. Eat bread and butter with it, if desired.

Egg Sandwiches with Watercress and Olives.

8. Slice some hard boiled eggs and lay on buttered bread. Mix some olives and watercress with mayonnaise dressing, and serve with the bread. Egg sandwiches combine well with sliced or potted ham, or with anchovy or herring--butter, or with apples.

Cottage or Cream Cheese Sandwiches.

9. Spread thin slices of rye or black bread with cheese. Combine with apples or olives, with or without lettuce and mayonnaise dressing.

Cabbage Salad with Bread, Butter and Bologna.

10. Prepare the salad in the morning, mix with mayonnaise dressing and carry in a glass or jar. Prepare the bread with butter and thin slices of bologna or ham. Eat the cabbage salad as an entree or with the sandwiches. Hard boiled eggs are a good addition.

Potato Salad with Black Bread and Butter and Bologna.

11. Serve the salad as an entree. Prepare thin slices of pompernickle with butter and bologna or ham, and combine with hard boiled eggs. Nuts may be substituted for eggs.

Peanut and Olive Sandwiches.

12. Remove the stones and cut the olives into small pieces, mix with diluted peanut butter, and season with lemon.

Spread on rye bread.

Egg Sandwiches with Ham or Chipped Beef.

13. Chop some ham or beef very fine. Prepare some eggs for scrambling, mix with the meat and finish like scrambled eggs. When cold spread on sandwiches.

Raw Beef Sandwiches.

14. Wash some freshly cut round-steak, dry and scrape. Spread on buttered triscuit or soda cracker. Combine with lettuce and French dressing. Serve at once.

Sandwiches with Sausage.

15. Spread thin slices of rye or black bread with butter. Cover with liver sausage, blood sausage or metwurst. Goose fat or leaf lard can be substituted for the butter or be omitted. Combine with tart apples. Onions and lettuce is also a good addition.

Meat Sandwiches with Tomatoes and Cucumbers.

16. Cut some cold boiled or roasted lean meat into thin slices and lay on buttered bread. Eat cucumbers with it.

CHAPTER V.

FOOD COMBINATIONS AND MENUS.

DO NOT MIX.

Meat and Cheese.

Cherries and Milk.

Fancy Summer Fruits and Onions.

Fancy Summer Fruits and Cucumber.

Nuts and Excess of Starchy Food.

Potatoes and Tomatoes.

Potatoes and Tart Fruits.

Potatoes and Fresh Yeast Bread.

Potatoes and White Bread.

Potatoes and Underground Vegetables.

Cooked Greens and Raw Greens.

Meat and Dates or Figs.

Pork and Sago.

Cucumber and Sago.

Strawberries and Tomatoes.

Strawberries and Beans.

Bananas and Corn.

Fat Pork and Cucumbers.

Pork and Sweet Fruits.

Pork and Fancy Fruits.

Pork and Corn.

Meat and Fish.

Raw Fruits and Cooked Vegetables.

Milk and Cooked Vegetables.

Milk and Meat.

Fresh Raw Fruits and Cooked Cereals.

Cooked Vegetables and Nuts.

Cheese and Nuts.

Boiled Eggs and Nuts.

Boiled Eggs and Canned Corn.

Boiled Eggs and Bananas.

Boiled Eggs and Fresh Pork.

Boiled Eggs and Cheese.

Bananas and Pork.

Bananas and Cucumbers.

Skim-milk and Fruit.

Cheese and Bananas.

Beans and Bananas.

GOOD COMBINATIONS.

Raw Fruits and Raw Cereals.

Raw Fruits and Raw Cereals and Nuts.

Raw Fruits and Raw Greens and Nuts.

Raw Cereals and Nuts.

Raw Cereals and Raw Milk.

Raw Cereals and Raw Vegetables.

Boiled Cereals and Boiled Milk.

Boiled Cereals and Boiled Cream.

Raw Greens and Meats or Eggs.

Boiled Greens and Meats or Eggs.

Fats and Acids.

Meats and Acids.

Cheese and Apples.

Cheese and Rye.

Eggs and Salted Meat.

Eggs and Acid Fruits.

Eggs and Greens.

Nuts and Apples.

Nuts and Bananas.

Almonds and Rice.

Nuts and Raisins.

Nuts and Dried Currants.

The harmony and disharmony between the different foods as mentioned above are only stated in a general way. Certain combinations are absolutely harmful to every individual, others are either harmful to certain temperaments, or, to mix them would mean a waste in the animal economy of the body.

REMARKS.

Use only one rich protein food at any meal.

Exceptions: A few nuts which are rich in fat may be eaten at the end of a meal where lean meat is served.

Milk and milk soups may be taken at the beginning of a meal where meat is served, but they should never be mixed with the meat dish or used at the end of a meal where meat is served.

CHAPTER VI.

LAXATIVE FOODS.

Fruit juices, plums, tomatoes, apples, pears, grapes, figs, fruit-soups, fruit-gruels, raisins, gelatines, corn, oats, spinach, oranges, carrots, parsnips, bran, oil, butter, cream, olives, yolks of eggs, pecans, walnuts, Brazil nuts, cucumbers, onions, greens.

CONSTIPATING FOODS.

Skim-milk, liquid foods, fine flour bread, potatoes, tapioca, white of eggs, gluten, mush, lean meat and cheese made from skim-milk.

MENUS.

A menu which is one-sided or combined wrongly, that is, one in which either protein, carbohydrates, minerals or fluids are provided in excess, leads to waste of nervous energy as well as to waste of nutritive material. A wrong combination creates an abnormal appetite for too much or too little food.

Each person should learn by experience to select the kinds of food which yield him nourishment and avoid those which disagree.

MENUS FOR BREAKFAST.

People who feel the need of laxative foods during the spring season will find here a number of suitable breakfast menus to choose from:

1. Cooked spinach or yellow dock or mustard greens or dandelion leaves with rye or wheat bread and butter. Eggs or bacon, if desired.

2. Finely mashed boiled beets or turnips or potatoes or carrots or parsnips with plenty of parsley and bacon or ham or cornbeef or chipped dried beef.

3. Rhubarb salad and lettuce with French or mayonnaise dressing. Cornmeal cakes or muffins.

4. Mushroom salad with lettuce and French dressing. Bread and butter.

5. Cooked cereal of rice or wheat or rye with hot cream or butter and cucumbers cut in halves.

6. Sliced bananas and grapefruit with nut dressing or with mayonnaise dressing.

7. Cabbage salad with mayonnaise dressing, hard boiled eggs and bread with butter.

8. Strained canned tomato juice and bananas with lettuce.

9. Fish cakes with steamed potatoes, parsley and butter. Black crusts.

10. Baked or plain boiled cauliflower with cold boiled beef or chipped beef.

11. Boiled cauliflower with tomato sauce and stale bread with butter and grated cheese.

12. Tomato puree with fried parsnip balls, black toast with butter.

13. Radishes, green onions, whole wheat bread and butter.

14. Asparagus salad with ham hash, bread and butter.

15. Cream of potato soup with black toast or raw carrots or celery.

16. Salted mackerel with creamed potatoes, a glass of milk, celery.

17. Apple salad with mayonnaise dressing, a slice of stale bread and a glass of milk.

18. Lettuce with syrup dressing and German pancakes with bacon.

19. French rolls with butter and boiled ham, black malt coffee.

20. Warm apple pie with lettuce and cheese, black malt coffee.

21. Apple salad, corn bread, creamed chipped beef.

22. Shredded wheat with strawberries and milk or cream.

23. Lettuce, baked potatoes, fish salad with mayonnaise dressing.

24. Warmed-over macaroni with tomato puree and cold grated cheese.

25. Macaroni with cream sauce and frankfurter.

26. Codfish cakes with cream rice or apple rice or apple salad.

27. Omelet with lettuce and stewed prunes or syrup dressing.

28. Apple rice with bacon or eggs or fish croquettes, celery.

29. Boiled onions with black bread and butter and bologna or frankfurter.

30. Bread fritters with apple sauce or with lettuce and syrup dressing.

31. Bacon with string beans, bread and butter, stewed prunes.

32. Lettuce with mayonnaise dressing and baked potatoes with creamed beef.

33. Celery with French dressing and fried sweet potatoes with cranberry sauce.

34. Corned beef hash with eggs and triscuits with butter.

35. Lettuce with syrup dressing and buckwheat cakes.

36. Grated carrots with lettuce and unfired bread with butter or nut-cream.

37. Turnip salad with lettuce and unfired bread with butter or nut-cream.

38. Lettuce with French dressing and cornmeal patties with cranberry sauce.

39. Lettuce with French dressing and mashed potatoes with buttermilk and bacon.

40. Apple salad with lettuce and black bread with cheese.

41. Pear salad with cranberries and celery. Unfired bread with butter or nut-cream.

42. Lettuce with French dressing and baked potatoes and eggs.

WHAT SHALL WE DRINK WITH OUR MEALS?

This question is often asked. It depends entirely on the quality and combination of food which is eaten.

A diet consisting of a variety of solids and vegetables with excessive fluids gives the stomach nothing to do; the contents pass at once into the intestines. Such mixtures are ingested instead of being digested; they cannot be fully utilized because the stimuli upon the drainage of the body is lacking.

If dry foods are eaten, such as sandwiches, rice, macaroni, potatoes or dry cereals, without the addition of fruits, vegetables or soups, a small amount of liquid should be taken. Such simple foods do not form a perfect meal, therefore milk or broths are preferable to water. Water is best taken from five to fifteen minutes before the meal or from one to two hours after meals. Black malt coffee is sometimes beneficial if one-half cupful is taken after or with meals. It acts like a tonic, especially if the liver is sluggish.

CHAPTER VI.

MENUS FOR DINNER.

Select menus suitable for the season of the year. In the spring-time use more of eggs, lamb, fish, green peas, spring chicken and egg-foods in the form of pancakes, omelets and puddings. During the summer eat very little meat. Use nuts, fish, eggs and milk foods. As the weather gets colder use more protein foods and carbohydrates. During the winter use a larger amount of dried legumes, nuts and meats, and more fatty foods. Add fruits and vegetables which are in season.

1. Apple salad with lettuce and broiled steak, shredded wheat with butter.

2. Cream of pea soup. Beef or roast pork with potato dumplings, stewed prunes.

3. Broiled chops with young peas and creamed potatoes. Oranges.

4. Tomato salad with lettuce. Veal with mushrooms and rice. Toast and coffee.

5. Cream of tomato soup. Veal chops with peas, stewed prunes.

6. Broth with egg. Spinach, hard eggs, tongue. Grapes or oranges.

7. Sweet potatoes with roast beef, tomato puree, celery. Black toast with coffee.

8. Apple salad with watercress, fish with shredded wheat or bread and butter.

9. Tomato jelly salad. Beef croquettes with tomato sauce and rice, celery.

10. Cream of potato soup. Cold beef with stewed prunes, bread and butter.

11. Bean soup. Cabbage or sprouts with mutton, bread and butter.

12. Raw oysters with lemon and apple salad, whole wheat bread and butter, celery.

13. Boiled veal or mutton with caper sauce and stuffed peppers, celery.

14. Barley soup with cracker. Roast duck with apple stuffing. Grapes or oranges.

15. Macaroni with grated cold cheese and lettuce salad.

16. Rice with grated cold cheese and lettuce salad.

17. Baked fish, boiled potatoes with parsley. Black toast with butter and coffee.

18. Meat soup with bread and butter. Fish salad. Apples or oranges.

19. Clam chowder. Omelet with lettuce and fruit sauce.

20. Pea soup with fried bread. Roast goose with apple sauce.

21. Baked potatoes with kidney stew. Black toast with butter.

22. Potato salad with lettuce and fish, black crusts.

23. Apple salad. Roast chicken with cranberry sauce. Steamed pudding with wine sauce.

24. Rice or barley soup with crackers. Corned beef with cabbage and creamed potatoes.

25. Tomato or apple salad with lettuce. Nuts.

26. Rice with tomato sauce. Nuts.

27. Rice with almond butter. Almonds.

28. Banana salad with rye nuts and lettuce. Nuts.

29. Pineapple salad with lettuce. Nuts.

30. Beef or fruit soup. Macaroni with cream.

31. Apple salad with lettuce, smoked eel with black bread.

32. Corned beef, boiled eggs, potatoes and cabbage.

33. Knorr’s pea soup with crackers. Stuffed peppers.

34. Roast pork ribs with apple filling. Oranges, black bread with butter, coffee.

35. Meat croquettes, beets, black bread and butter.

36. Roast chicken with sprouts. Cranberry sauce. Steamed rice pudding.

37. Green peas with dumplings and fried bacon, celery.

38. Tripe with tomato sauce and sprouts, triscuit with butter.

39. Apple salad with blood sausage, bread and butter.

40. Tomato salad with lettuce and fish, bread and butter.

41. Lamb stew with dumplings and green peas.
42. Lettuce salad. Mashed carrots and baked beans with lemon.
43. Pork with sauerkraut and dumplings.
44. Raw carrots and lettuce salad. Pork and lentils.
45. Beefsteak with eggs and potatoes, celery.
46. Pea soup with crackers. Fish with apple salad, celery.
47. Rice with frankfurters. Nuts.
48. Sour roast with potato dumplings and lettuce salad. Stewed prunes.
49. Broth with egg. Apple salad with onions and lettuce, pork chops.
50. Pea soup with toast. Fish with apple rice. Black coffee and crusts.
51. Apple salad with onions and lettuce, liver sausage, black bread.
52. Milk soup. Plum pudding with brandy sauce, celery.
53. Game or pork with sauerkraut and potato dumplings.
54. Tongue with mushroom sauce and baked potatoes. Crusts and coffee.
55. Apple salad with cottage cheese, olives, bread and butter.
56. Boiled beef with string beans, steamed potatoes with white sauce.
57. Baked oatmeal with cranberry sauce and celery.
58. Carrot salad with lettuce. Lima beans with cold pork. Oranges.
59. Fish with potato salad and black crusts. Grapes.
60. Roast mutton with peas and baked potatoes, celery.
61. Bean soup with raw carrots, bread and butter.
62. Barley soup with soda crackers. Swiss cheese and apple salad.
63. Lettuce salad with omelet and stewed prunes or cranberries.
64. Tomato and lettuce salad with pork tenderloin. Oranges, bread and butter.
65. Mashed carrots or beets with lemon, and fat or lean pork. Green grapes.
66. Pea soup with fried bread. Calves' liver with apple salad.
67. Lentil soup with fried bread. Codfish balls with apple sauce.
68. Rice and tomato soup. Boiled beef with horse-radish sauce and cabbage.
69. Milk soup. Bologna, toast and butter.
70. Salad of tomatoes or apple with mayonnaise dressing. Roasted chestnuts.
71. Calves' tongue with mushroom sauce and rice. Crackers with butter.
72. Lettuce salad. Fried eggplant with lemon and beefsteak, string beans.
73. Blue or white cabbage with cold or warm roast pork and baked potatoes or apples.

74. Cabbage rolls with potatoes and white sauce. Bread pudding.

75. Raw sweet corn and tomato salad with French dressing. Bread and butter.

76. Chicken soup with rice. Roast chicken with stuffed apples and cranberry compote, celery.

77. Green pea soup with fried bread. Breaded sour goose with potatoes and apple sauce.

78. Bean soup with cream. Apple dumplings with lemon sauce.

79. Celery and apple salad with mayonnaise dressing. Baked squash with lemon and beefsteak. Grapes.

80. Boiled cabbage with egg dressing. Bread pudding with stewed prunes or fruit sauce.

81. Apple and pineapple salad with whipped cream. Almonds and raisins.

82. Apples and lettuce salad. Buckwheat pancakes with syrup dressing. Nuts.

83. Corn bread, 3 to 6 ounces of canned strained tomato juice. Nuts.

84. Cream of corn soup with black crusts. Nuts.

85. Potato salad with cottage cheese and lettuce.

86. Boiled or steamed bread pudding with tomato sauce or fruit sauce.

87. Lentils with onions. Apple bread pudding, black coffee.

88. Tomato soup with crackers. Warm pop corn or roasted chestnuts.

89. Fresh codfish with horse-radish sauce and boiled potatoes. Black bread with butter.

90. Peanut roast with tomato sauce and celery.

91. Polenta with apricot or cranberry sauce and cheese.

92. Boiled whole wheat with butter or hot cream and cucumbers. Nuts.

93. Baked rolled oats with cranberry sauce, celery.

94. Smoked goose breast with apple salad and black bread.

95. String bean soup. Lima beans or cow beans with bacon. Oranges.

96. Asparagus salad. Spring lamb with caper sauce, bread and butter.

97. Cherry soup. German pancakes with lettuce and syrup dressing.

98. Blackberry soup. Cereal or bread omelet with lettuce and syrup dressing.

99. Milk soup with sago. German pancakes with gooseberry compote.

100. Wine soup with wafers. Fish-pudding with apple sauce.

101. Milk soup with buckwheat groats. Boiled fish with potatoes and currant sauce.

102. Plum soup with zwieback. Steamed or plain bread pudding.

103. Bread soup with apples. Liver pudding with tomato puree.

104. Celery-root salad with crusts. Plum pudding with wine sauce.

105. Bran or bread soup. Apple salad with grated cheese.

106. Milk or huckleberry soup. Unleavened apple pancakes.

107. Clabber milk with cream and grapenuts or stale bread. Nuts if desired.

108. Corn bread with apple salad and lettuce. Nuts.

109. Plain milk rice with currants. Nuts.

110. Oatmeal soup. Ham with kale and fried potatoes.

111. Bread dumplings with stewed prunes or pears, celery.

112. Fried herring with potato salad. Apple-bread pudding.

113. Buttermilk soup with dried fruit. Nuts if desired.

114. Meat cakes with mashed carrots or beets and lettuce salad.

115. Peas with codfish, butter and bread.

116. Vegetable pudding with tomato puree and yellow dock.

117. Bread fritters with lettuce and syrup dressing or stewed prunes.

118. Baked oats or barley with bologna. Nuts if desired.

119. Whole wheat or rice with bologna. Nuts if desired.

120. Plum salad with raw rolled rye or wheat. Walnuts.

121. String bean salad. Fish pudding with tomato puree or apple sauce, celery.

122. Salisbury steak with fried parsnip and lettuce salad.

123. Steamed mashed pumpkin with pickled tongue or corned beef. Black bread with butter.

124. Watercress salad. Pork tenderloin with tomato puree and roasted yellow turnips.

125. Lettuce salad with mayonnaise dressing. Apple or tomato rice with fish or boiled beef.

126. Lettuce or celery salad with mayonnaise dressing. Currant or cherry rice with fried eggs.

127. Asparagus with cream sauce and cold boiled ham and bread.

128. Empire salad. Bread pudding with wine sauce.

129. Kidney soup with rice and egg. Cooked celery-roots and kidney hash on toast.

130. Huckleberry soup with white of egg. Roman meal cakes with lettuce and syrup dressing.

131. Dried cherry soup with zwieback. Steamed or baked rice pudding with lettuce and syrup dressing.

132. Barley soup with prunes. Cold sliced beef with mustard sauce and string beans.

133. Asparagus salad. Broiled chicken with tomato puree, triscuit with butter.

134. Blackberries with one glass of rich milk and bananas. Nuts if desired.

135. Banana and apple salad with lettuce, French or mayonnaise dressing. Nuts.

136. Tomato and cucumber salad with lettuce, French or mayonnaise dressing. Fish with bread and butter.

137. Watercress salad with French dressing. Veal stew with mushrooms and rice.

138. Cabbage salad with mayonnaise dressing. Hard boiled eggs with whole wheat bread and butter.

139. Kidney soup with rice. Brown kidney stew on toast with asparagus.

140. Noodle soup. Boiled brisket with horse-radish sauce, bread and butter.

141. Bread soup with cream. Cold sliced boiled meat with string beans, triscuit with butter.

142. Cherry soup. Corn meal pudding with lemon sauce.

143. String bean soup. Fried left-over pudding with fruit sauce.

144. Blue fish with steamed potatoes, parsley and butter. Apple-bread pudding.

145. Spinach with egg. Fried fish with crust-potatoes and apple sauce. Oranges, toast with butter, black unsweetened coffee.

146. Green pea soup with fried bread. Pickled tongue with fried parsnips and lettuce salad. Green grapes.

147. Fish croquettes with apple salad. Steamed rice pudding with wine sauce. Black unsweetened coffee.

148. Apple snow on leaves of lettuce. Boiled white fish with drawn butter sauce and steamed potatoes, Roman meal cakes with apple sauce. Black unsweetened coffee.

149. Stuffed tomatoes with lettuce. Plum pudding with butter sauce, celery. Black coffee.

150. Lettuce and apple salad with grated Swiss cheese. Pumpkin pie with black coffee.

151. Artichokes with mayonnaise dressing. Broiled steak with baked potatoes and sprouts. Blue or red grapes.

152. Rice and tomato soup. Fillet of beef with mashed potatoes and stewed dried mushrooms. Apple tart with black unsweetened coffee.

153. Creamed onions. Fried chicken with cranberry compote and endive salad. Triscuit with butter, black unsweetened coffee.

154. Tomato and celery salad with mayonnaise dressing. Baked beans with lemon. Boston brown bread, coffee.

155. Apple sago with whites of egg and cream. Baked white fish with lemon and creamed potatoes. Apple pudding, black coffee.

156. Cantaloupe with lemon. Sliced bananas with whipped cream. Pecan or almond nuts.

157. Green pea broth with crackers and butter. Fried oysters with sauerkraut, bread and butter. Apple fritters with black unsweetened coffee.

158. Tomato and lettuce salad. Navy or butter beans with carrot puree and fried beachnut bacon. Toast with butter and black unsweetened coffee.

159. Broth with egg and crackers with butter. Macaroni and cheese with sprouts. Tomato gelatine.

160. Eggs with spinach and buttered toast. Cherry pie with black unsweetened coffee. Oranges.

161. Tomato puree and cabbage rolls with fried parsnips. Fruit gelatine.

162. Banana and date salad with lettuce. Pecans.

163. Barley soup. Baked fish and potato puree. Fried black toast with butter and unsweetened coffee.

164. Veal broth with sago. Veal with bread dressing, stewed prunes or rhubarb. Black coffee.

165. Watermelon. Meat croquettes with mashed or pickled beets, celery.

166. Cherries, apricot and lettuce salad. Nuts.

167. Cream of tomato soup. Corn bread with spinach and boiled eggs. Baked apples in gelatine.

168. Cream of celery soup. Cold boiled beef with olives and endive salad. Bread pudding with wine or fruit sauce.

169. Cream of potato soup. Smoked eel with apple and lettuce salad. Oranges, black toast and black unsweetened coffee.

CHAPTER VII.

MENUS FOR SUPPER.

1. Rice soup with crackers. Plum pudding with wine sauce.

2. Corned beef with sprouts, zwieback with butter and apple sauce.

3. Clam chowder with soda crackers and fruit.

4. Milk soup with black toast. Grapes.

5. Apple salad with bacon and black toast. Oranges.

6. Pea soup with crackers or raw celery. Grapes.

7. Apple salad with fish and black toast. Grapes or oranges.

8. Stewed prunes with cream and shredded wheat.

9. Artichokes with dressing. Creamed beef on toast.

10. Potato soup with shredded wheat and raw celery.

11. Barley soup with soda crackers and raw celery.

12. Sprouts with pickled tongue. Banana gelatine.

13. Lettuce with omelet and apple sauce.

14. Beef soup with rice. Boiled beef with sprouts, prunes.

15. Tomato soup with shredded wheat, raw celery.

16. Milk-rice with soda crackers or stale black bread.

17. Broth with egg and toast. Puffed wheat with butter and fried bacon.

18. Three-fourths to one pint of fresh milk with tomato toast.

19. Meat soup with rice and egg. Triscuit, butter.

20. String bean salad with mayonnaise dressing. Bran bread with butter, bacon.

21. Milk-or apple-rice with codfish cakes. Raw celery.

22. Cream of pea soup with soda crackers. Raw celery.

23. Date and lettuce salad with bread and butter.

24. Buckwheat gruel with cream and toast with honey or syrup.

25. Huckleberry pie with fresh milk or malt coffee.

26. Sago gruel with milk or cream and toast with apricot jam.

27. Baked bananas with black or bran bread and butter, malt coffee.

28. Blue grapes. Left-over steamed pudding with wine sauce.

29. Black stale bread with fig butter and rich fresh milk.

30. Fruit soup of plums or huckleberries, with whites of egg and toast with butter.

31. Bread soup with cream or butter, and soaked French prunes.

32. Whey or buttermilk soup, with soaked French prunes.

33. Stewed prunes with cream. Lemon pie with black malt coffee or milk.

34. Poached or soft boiled eggs, with bread and butter.

35. Apple or cranberry pie with hot or cold milk.

36. Baked apples with cream. Shredded wheat or bran bread with butter, bacon.

37. Warm chocolate pudding with cream and one glass of milk with toast.

38. Red fruit pudding with cream. One glass of milk with toast.

39. Potato soup with black bread, raw celery.

40. Apple or cranberry pie. Pine kernels.

41. Fruit or vegetable toast with fried bacon. Oranges.

42. Knorr's pea soup with cream and crackers. Raw celery.

43. Musk or watermelon. Creamed chipped beef, triscuit with butter.

44. Warm boiled custard with fruit sauce, black crusts or toast.

45. Barley soup with soda crackers. Creamed fish with baked apples.

46. Green pea soup with fried bread. Fruit cake and cereal coffee, raw celery.

47. Broth with egg. Steamed pudding with fruit or tomato sauce, raw celery.

48. Clam broth with crackers. Egg toast with fruit sauce.

49. Buckwheat gruel with cream. Fish with apple sauce and toast with butter.

50. Sago gruel with cream. Huckleberry pie with milk or coffee.

51. Baked bananas. Apple bread pudding with milk or coffee.

52. Blue grapes. Fried steamed pudding, or hominy cakes with fruit sauce.

53. Rice with milk. Black toast with fig butter or honey.

54. Blue plum soup with sago and whites of egg. Pumpkin pie with coffee.

55. Bread soup. Chops or beef with apple salad and mayonnaise dressing.

56. Pea broth. Tripe with tomato or whey sauce and toast with butter.

57. Melon with lemon or berries. Codfish cakes with bread and butter.

58. Cream of corn soup with tomato toast.

59. Rice flour with hot cream or milk. Toast with eggs.

60. Milk rice with soda crackers or toast.

61. Clear broth with crusts. Eggs and macaroni with fruit sauce.

62. Apple salad, puffed wheat with butter and fried bacon.

63. Broth with egg and cracker. Sprouts with lamb, toast with butter. Oranges.

64. Fresh milk with tomato toast.

65. Apple or tomato salad with mayonnaise dressing. Fish with lemon and toast with butter.

66. Apple and celery salad. Fruit cake with black coffee.

67. Raspberries or strawberries, dry toast or shredded wheat, one or two glasses of rich fresh milk.

68. Tomato or blackberry toast, with one or two glasses of rich milk.

69. Fruit gelatine with cream. Sandwiches, black coffee.

70. One or two glasses of sterilized blackberry juice with zwieback. Omelet with fruit sauce.

71. Clabber milk with cream and dry toast. Nuts if desired.

72. Lemon pie with fresh milk, or sand tart with fruit salad.

73. Raw huckleberries and zwieback with sweet butter. Nuts if desired.

74. Asparagus or artichokes with mayonnaise dressing. Sandwiches.

75. Boiled skim-milk with black bread.

76. Meat soup with barley. Apple salad or bread with Swiss cheese or cream cheese or cottage cheese.

For additional menus see recipes of soups, gelatines, salads, fish, sandwiches and egg foods.

Many of the above menus are suitable for children and for people of sedentary habits.

For those who require a liberal amount of nutritious food, it is easy to make up a number of additional menus from light protein foods for the evening meal, such as: Cream cheese, cottage cheese, Swiss cheese, fish, lamb chops, meat cakes (prepared from left-over cooked meats), eggs, pancakes (prepared with eggs or cream), fried egg-toast, sausages, legume soups, etc. Apples, tomatoes and prunes combine well with all the above mentioned foods.

CHAPTER VIII.

POOR MAN'S BILL OF FARE.

Suitable for people who perform hard manual labor, out of doors, and for those who are not steadily employed.

Sample Menu.

How to feed a family of five (2 adults and 3 children under 12 years of age) on $5.00 per week or 14 cents per person per day--71 cents per day for all.

BREAKFAST.

Cereal salad with apples and onions.

Cost in Cents.

Rylax or rolled wheat 2½■ cups 2½■ Apples 3 large 5 Cotton seed oil 3 tablespoons 2 Lemon ½■ 1 Onion 1 whole ½■

DINNER.

Lettuce with syrup dressing. Dried green peas with dumplings and fried bacon.

Lettuce 1 head 2 Syrup 3 tablespoons 1 Lemon or vinegar 2 tablespoons -- Cotton seed oil 3 tablespoons 2 Onion 1 whole ½■ Peas 1 pound 5 Flour 1½■ cups 3 Bacon ½■ pound 15

SUPPER.

Cream of tomato soup with dry toast.

Tomatoes 1 can 8 Soup stock 1 quart 5 Milk 1 quart 8 Butter 3 tablespoons 4 Flour 4 tablespoons ½■ Toast 7 large slices 4 -------- TOTAL 69 Cents

If porridge with milk is desired for breakfast, substitute a quart of milk in place of apples, oil, lemon and onion. Use one and three-fourths cup of rolled wheat or rye in place of two and one-half cups. If sugar is necessary, add fifteen prunes or five level tablespoons of sugar. During the summer, substitute carrots or cucumbers for the sweets. Raw, sweet or sub-acid fruits do not combine well with cooked cereals. Raw fruits and raw cereals is a better combination.

In order to reduce the cost of living to 10 cents per person per day or 50 cents per day for all, leave out the fat meat costing 15 cents, and some of the butter, replacing it by cooking oil. It is easy to modify the diet or add to it in a given direction. If more protein is required, a boiled egg or a few nuts may be added to the breakfast. If more fuel is needed, it can be added in the form of soup, fruits or fat. In comparing the value of 1 pound of legumes with 1 pound of lean meat and the additional fatty and green foods that are necessary with a meat diet, the housewife will realize that she must either have a big purse for the bills of fare with meat, or starve her family if they do not like legumes.

Ten cents per day is a small sum for a useful citizen to live on, yet thousands of people are compelled to do so every year, and for these the following pages might be of assistance.

Economical management, self-denial and abstinence from luxuries are the lessons to be studied. Look over the chapter on protein foods carefully. Never economize in these in order to buy cake, pastry or sweets. All who, for some reason or other, have to fight off starvation, will find that whole wheat bread and pure water or oatmeal porridge are the most perfect foods to keep them in fair health. They prevent diseases which might be the result of such conditions. To keep up on tea, coffee, sugar, white bread and liquor might result in dangerous breakdowns, insanity, murder and suicide. Coffee, tea and alcohol are medicines; they are valuable at times for the sick, when the system cannot digest food, or under conditions where not sufficient natural food can be obtained. On such occasions they may prevent disease and death.

Monthly total receipts, $ ....

Savings, $ ....

Knowledge of bookkeeping is a necessity for systematic homekeeping. The experience gained from a household book with careful planning for one year is of more value than the experience gained from five years of unsystematic housekeeping. Wise management of a home will enable a family with a moderate income to enjoy comforts and pleasures, of which a family in better circumstances, but with poor and unwise management, is deprived.

“Time is money,” therefore careful planning of the time that is expended for work, rest, recreation and outdoor life is as important as management of finances. Many women waste much valuable time with nonsensical details in the line of cleaning, cooking and fancy sewing. This abnormal amount of manual work and neglect of mental development is generally followed by worry and poor health, as the result of an anemic brain. In those conditions mental healers perform miraculous cures either by changing the activity of the mind or by paralyzing it to the extent of ignoring the plain facts of nature, and by denying the testimony of the senses.

The modern household is full of unwholesome things,--too many pictures, carpets, curtains and other ornaments, and too many salted, peppered, sugared and greasy artificial foods, with a lot of unnecessary dishes and utensils. A woman who enjoys spending all her time in drudgery, values herself below the poorest paid day-laborer.

To save time and strength means investing time and strength on more important subjects, such as harmonious conversations, out of door exercise, attending lectures, and the teaching of the laws of health and hygiene to the young, which cannot be begun too early. Unsystematic management of household work and the care of children has broken up many a home.

HOW TO FEED A FAMILY OF FIVE (2 ADULTS AND 3 CHILDREN) ON $3.50 PER WEEK OR 10 CENTS PER PERSON PER DAY DURING FALL AND WINTER.

Staple foods for two weeks. Cost in cents. Flour 10 pounds 35 Graham or whole wheat bread 3 loaves 15 Rye bread 1 loaf 10 Sugar 1 pound 05 Cereal coffee 1 package 20 Coffee beans ½■ pound 10 Bran 1 package 15 Roman meal 1 package 15 Rolled or steel-cut oats 1 package 10 Rice 2 pounds 10 Potatoes 4 pounds 20 Tomatoes 3 cans 25 Bacon ½■ pound 15 Dry peas 2 pounds 10 Dry beans 2 pounds 10 Lentils 1 pound 05 Corn meal 3 pounds 10 Dried prunes 4 pounds 25 Cheese ½■ pound 10 Onions 1 pound 05 Macaroni 1 pound 10 Salt 1 bag 05 Vinegar 1 pint 05 Cotton seed oil 2 quarts 50 Apples 6 pounds 25 Syrup 1 pint 05 Pumpkin 1 10 Eggs ½■ dozen 25 Rolled rye 1 package 15 Butter 2 pounds 45 Corn starch 1 package 10 Rolled wheat 1 package 10 ---- Total $4.95

SATURDAY.

=Breakfast.=--Roman meal cakes with lettuce and syrup dressing.

=Dinner.=--Hot skim-milk with black crusts. Macaroni with grated cheese.

=Supper.=--Meat soup with tomatoes and rice. Fried bread with apple sauce.

Cost of additional foods for Saturday: One gallon of skim-milk 5 cents, lettuce 5 cents, beef brisket 15 cents,--total 25 cents.

SUNDAY.

=Breakfast.=--Baked pumpkin, lettuce salad with raw rolled rye.

=Dinner.=--Warmed-over macaroni with soup stock, meat with tomato sauce.

=Supper.=--Hot skim-milk with black crusts or stale bread.

Cost of additional foods for Sunday: None.

MONDAY.

=Breakfast.=--Oatmeal porridge with butter or left-over boiled skim-milk.

=Dinner.=--Mixed boiled dinner of beans, potatoes and carrots.

=Supper.=--Soup from left-over scraps of tomatoes and meat, thickened with fat and flour, or pumpkin pie and black coffee or hash.

Cost of additional foods for Monday: Carrots and parsley 5 cents,--total 5 cents.

REMARKS: A portion of the skim-milk should be boiled on Sunday and balance be put in a pan for cottage cheese.

On Monday put one-half of the two pounds of beans in an earthen pot to bake before the carrots and potatoes are added. Preserve the baked beans with oil and keep in a cool place until Thursday.

TUESDAY.

=Breakfast.=--Rice with carrots and frankfurters.

=Dinner.=--Green pea soup. Codfish with butter sauce and potatoes with parsley.

=Supper.=--Left-over soup. Egg toast with stewed prunes or apple sauce.

Cost of additional foods for Tuesday: Frankfurters, 5 cents, fish, 15 cents,--total 20 cents.

WEDNESDAY.

=Breakfast.=--Corn meal mush or cakes with raw or stewed apples or prunes.

=Dinner.=--Cottage cheese with apple or potato salad and lettuce.

=Supper.=--Bread soup. Apple pancakes with lettuce salad.

Cost for additional foods for Wednesday: None.

THURSDAY.

=Breakfast.=--White or black toast with whey sauce (use whey which is drained from cottage cheese).

=Dinner.=--Lettuce salad. Raw carrots with baked beans. Brown bread with butter.

=Supper.=--Tomato and meat soup with toast. Celery.

Cost of additional foods for Thursday: Lettuce 5 cents, carrots 5 cents, parsley and celery 5 cents, Boston brown bread 10 cents, soup bone 5 cents,--total 30 cents.

FRIDAY.

=Breakfast.=--Oatmeal porridge with butter and syrup.

=Dinner.=--Milk soup with Roman meal. Fried herring and potatoes with parsley.

=Supper.=--Lentil soup with fried bread.

Cost of additional foods for Friday: Skim-milk 5 cents, herring 10 cents,--total 15 cents.

Total expenditure for the first week, 95 cents.

SATURDAY.

=Breakfast.=--Corn meal cakes with lettuce and syrup dressing.

=Dinner.=--Potato soup (prepared with fat, flour and skim-milk). Noodles with stewed prunes.

=Supper.=--Hot skim-milk with stale bread.

Cost of additional foods for Saturday: None.

REMARKS: Bake bread from one-half of the ten pounds of flour, mix with Roman meal instead of whole wheat flour.

SUNDAY.

=Breakfast.=--Bran muffins with stewed prunes.

=Dinner.=--Water rice with raisins or currants. Nuts.

=Supper.=--Corn starch pudding with stewed prunes and black crusts.

Cost of additional foods for Sunday: 1 pound of nuts 10 cents, raisins 5 cents,--total 15 cents.

REMARKS: Prepare the corn starch pudding on Saturday. Use balance of skim-milk with one-half water, a piece of butter, the yolk of an egg, some salt and a little sugar.

MONDAY.

=Breakfast.=--Rolled rye with butter and syrup.

=Dinner.=--Noodles with tomato sauce and liver.

=Supper.=--Potato soup with parsley and toast. (Prepare with fat, flour and left-over gravy from liver.)

Cost of additional foods for Monday: Liver 15 cents,--total 15 cents.

TUESDAY.

=Breakfast.=--Corn bread or fried mush with lettuce and syrup dressing.

=Dinner.=--Dried peas with flour dumplings and bacon sauce. Stewed prunes if desired.

=Supper.=--Corn meal porridge with skim-milk.

Cost of additional foods for Tuesday: Skim-milk 5 cents, lettuce 5 cents,--total 10 cents.

WEDNESDAY.

=Breakfast.=--Oat meal porridge with butter.

=Dinner.=--Lima beans with frankfurters and raw carrots.

=Supper.=--Stale bread with prune jam. Fresh milk diluted with barley water.

Cost of additional foods for Wednesday: Beans 5 cents, frankfurters 10 cents, fresh milk 10 cents, carrots and parsley 5 cents,--total 30 cents.

THURSDAY (Thanksgiving).

=Breakfast.=--Rolled wheat porridge with butter.

=Dinner.=--Apple salad with lettuce. Blood or liver sausage with rolled rye or black bread or baked oatmeal with cranberry sauce and celery.

=Supper.=--Tomato and lentil soup with fried bread.

Cost of additional foods for Thursday: Lettuce 5 cents, sausage 15 cents,--total 20 cents.

FRIDAY.

=Breakfast.=--Porridge from any kind of cereal with butter.

=Dinner.=--Cooked greens (pick some mustard or yellow dock on the street). Bread or flour dumplings with creamed fresh or salted codfish.

=Supper.=--Milk soup from stale bread and skim-milk.

Cost of additional foods for Friday: Fish 10 cents, skim-milk 5 cents,--total 15 cents.

Expenditure for staple foods $4.95 Additional expenditure for first week .95 Additional expenditure for second week 1.10 ---- Total $7.00

Staple Food for Two Weeks: Cost in Cents. Baking powder 1 can 15 Dried apples 2 pounds 15 Pearl barley 2 pounds 10 Flour 10 pounds 35 Sugar 1 pound 05 Rice 2 pounds 10 Eggs ½■ dozen 25 Apples 6 pounds 25 Leaf lard 2 pounds 10 Shoulder of mutton 3 pounds 15 Dried peas 2 pounds 10 Beans 2 pounds 10 Lentils 2 pounds 10 Bacon ½■ pound 15 Corn meal 3 pounds 10 Rolled rye 1 package 15 Oats 1 package 10 Wheat 1 package 10 Onions 1 pound 05 Cabbage 1 head 05 Lettuce 3 heads 05 Black bread 1 loaf 10 Whole wheat flour 2 pounds 10 Buckwheat flour 1 package 15 Potatoes 4 pounds 20 Cotton Seed Oil 2 quarts 50 Cheese ½■ pound 10 Apples 6 pounds 25 Butter ½■ pound 20 Tomatoes 3 cans 25 Milk delivered for two weeks 1 quart per day 1.25 Crackers 1 package 05 Nuts 2 pounds 20 ---- Total $6.05

SATURDAY.

=Breakfast.=--Mixed rolled rye and wheat porridge with butter and syrup.

=Dinner.=--Cabbage with mutton and bread and butter.

=Supper.=--Soup of mutton with rice and crackers. One-half quart of milk with barley water and toast for two children.

Cost of additional foods for Saturday: None.

REMARKS: Prepare sufficient bread for two weeks. If cabbage is left over, prepare it with fat, vinegar and flour and keep for Tuesday.

SUNDAY.

=Breakfast.=--Lettuce with syrup dressing and buckwheat cakes.

=Dinner.=--Rice soup with milk and raisins. Nuts.

=Supper.=--Left-over meat soup and bread for three. Milk and toast for two children.

Cost of additional foods for Sunday: None.

MONDAY.

=Breakfast.=--Oatmeal porridge with hot milk.

=Dinner.=--Lettuce with syrup dressing. Roman meal cakes. Hash of mutton.

=Supper.=--Baked apples in oil with black bread and residue of leaf lard with fried onions. One pint of milk and toast for two children.

Cost of additional foods for Monday: None.

REMARKS: Cut the leaf lard very fine, fry it in a pan with apples and a little oil.

TUESDAY.

=Breakfast.=--Cornmeal mush with hot milk.

=Dinner.=--Bean soup with bread. Cabbage and frankfurters.

=Supper.=--Pearl barley porridge with milk and cracker (for all).

Cost of additional foods for Tuesday: Frankfurters 5 cents,--total 5 cents.

WEDNESDAY.

=Breakfast.=--Three raw apples with black bread and lard.

=Dinner.=--Noodles and kidney stew. Bread if desired.

=Supper.=--Cream of green pea soup with bread and celery.

Cost of additional foods for Wednesday: Celery 5 cents, kidney 5 cents,--total 10 cents.

THURSDAY.

=Breakfast.=--Mixed rolled rye and wheat porridge with hot milk.

=Dinner.=--Mixed boiled dinner of beans, carrots and potatoes.

=Supper.=--Milk of soup for all.

Cost of additional foods for Thursday: Carrots and parsley 5 cents,--total 5 cents.

REMARKS: Keep one-half of the beans separate and bake for Sunday.

FRIDAY.

=Breakfast.=--Cornmeal pancakes with lettuce and syrup dressing.

=Dinner.=--Cream of corn soup. Meat croquettes and stewed dried apples. Bread.

=Supper.=--Bread soup with milk (for all).

Cost of additional foods for Friday: Canned corn 10 cents, Hamburg steak 5 cents, skim-milk 5 cents, lettuce 5 cents,--total 25 cents.

REMARKS: Prepare the corn soup with fat and flour, then add hot skim-milk. Use one pint of fresh milk for the bread soup and the balance skim-milk.

Total Expenditure for the week 50c.

SATURDAY.

=Breakfast.=--Oatmeal porridge with hot milk.

=Dinner.=--Baked noodles with milk and frankfurters.

=Supper.=--Mustard greens or yellow dock with lentils. Milk and toast for two children.

Cost of additional foods for Saturday: Frankfurters 5 cents, total 5 cents.

SUNDAY.

=Breakfast.=--Three raw apples and black bread with lard.

=Dinner.=--Lettuce salad with French dressing. Baked beans and bread.

=Supper.=--Milk toast for all.

Cost of additional foods for Sunday: Lettuce 5 cents, milk 5 cents,--total 10 cents.

REMARKS: Re-boil the skim-milk from Friday for cooking or baking.

MONDAY.

=Breakfast.=--Lettuce with syrup dressing. Cornmeal pancakes.

=Dinner.=--Milk soup with Roman meal. Bran biscuits with cheese and stewed dried apples.

=Supper.=--Cream of tomato soup with toast and celery.

Cost of additional foods for Monday: Celery 5 cents,--total 5 cents.

TUESDAY.

=Breakfast.=--Chopped apples with syrup dressing and raw rolled rye.

=Dinner.=--Cream of lentil soup. Tripe with tomato sauce and potatoes.

=Supper.=--Toast with apple sauce and hot milk diluted with barley water.

Cost of additional foods for Tuesday: Tripe 10 cents,--total 10 cents.

WEDNESDAY.

=Breakfast.=--Rolled wheat porridge with butter.

=Dinner.=--Mustard greens and unleavened pancakes with syrup or fruit sauce.

=Supper.=--Cream of pea soup with toast.

Cost of additional foods for Wednesday: Skim-milk 5 cents,--total 5 cents.

REMARKS: Flavor the greens with bacon. Use skim-milk and three eggs for the pancakes. Set part of the skim-milk for cottage cheese.

THURSDAY.

=Breakfast.=--Oatmeal porridge with hot milk.

=Dinner.=--Lima beans with potatoes and frankfurters or bologna.

=Supper.=--Apple pie with hot milk.

Cost of additional foods for Thursday: Frankfurters 5 cents,--total 5 cents.

FRIDAY.

=Breakfast.=--Buckwheat cakes with lettuce or yellow dock and syrup dressing.

=Dinner.=--Lentil and tomato soup. Cottage cheese with apple salad.

=Supper.=--Bread pudding with fruit sauce.

Cost of additional foods for Friday: Lettuce 5 cents,--total 5 cents.

Expenditure for staple foods $6.05 Additional Expenditure for first week .50 Additional Expenditure for second week .45 ---- Total $7.00

HOW TO FEED A FAMILY OF FIVE ON $5.00 PER WEEK OR 14 CENTS PER PERSON PER DAY DURING THE FALL AND WINTER.

Buy the same staple foods as suggested for the foregoing menus; add to it: Oranges, bananas, cream, peanut-butter, eggs, bacon, cheese, tomatoes, apples, rice, peas, celery, string beans, grapes or other fruits or vegetables.

HOW TO FEED A FAMILY OF FIVE (2 ADULTS AND 3 CHILDREN) ON $3.50 PER WEEK OR 10c. PER DAY DURING SPRING AND SUMMER.

Stale, whole wheat, graham and Cost in Cents. white bread 3 loaves 25 Flour 10 pounds 35 Stale black bread 2 loaves 15 Cereal coffee 1 package 20 Coffee beans ½■ pound 10 Bran 1 package 15 Roman meal 1 package 15 Cream of wheat 1 package 20 Rice 6 pounds 25 Potatoes 4 pounds 20 Tomatoes 3 cans 25 Bacon ½■ pound 15 Green dried peas 2 pounds 10 Lima beans 2 pounds 10 White beans 2 pounds 10 Corn meal 4 pounds 10 Dried prunes 2 pounds 10 Salt 1 bag 05 Vinegar 1 pint 05 Cotton seed oil 1 quart 25 Apples 6 pounds 25 Syrup 1 pint 05 Rolled rye 1 package 15 Rolled wheat 1 package 10 Corn starch 1 package 10 Butter ½■ pound 20 Eggs 2 dozen 35 Peanut butter 1 jar 25 Dried apricots 2 pounds 10 Onions 1 pound 05 ---- $4.85

REMARKS: Use plenty of parsley, pick green leaves such as mint, yellow dock, mustard greens and others on the road or in the country. Keep the eggs on ice or in salt water in a cool place.

SATURDAY.

=Breakfast.=--Mustard greens on toast.

=Dinner.=--Lettuce salad with baked beans and bread with butter.

=Supper.=--Rice and tomato soup with cracker or fried bread.

Cost of additional foods for Saturday: Lettuce 5 cents,--total 5 cents.

SUNDAY.

=Breakfast.=--Cereal salad with apples, onions and lettuce.

=Dinner.=--Steamed pudding with apricot sauce.

=Supper.=--Fresh milk and toast with tomato or apricot jam.

Cost of additional foods for Sunday: Milk 10 cents,--total 10 cents.

MONDAY.

=Breakfast.=--Cream of wheat porridge with butter and raw cucumbers.

=Dinner.=--Green pea soup with raw carrots. Left-over pudding.

=Supper.=--Buttermilk rice with prunes.

Cost of additional foods for Monday: Carrots 5 cents, buttermilk 5 cents,--total 10 cents.

REMARKS: Cook sufficient pea soup for two meals. (Use two-thirds of the two pounds of peas.)

TUESDAY.

=Breakfast.=--Mashed potatoes with buttermilk and bacon sauce. Black toast.

=Dinner.=--Apple salad with peanut dressing and raw rolled rye or wheat.

=Supper.=--Cream of pea soup with toast and celery or parsley.

Cost of additional foods for Tuesday: Fresh milk 10 cents,--total 10 cents.

REMARKS: Use a pint of milk for the left-over pea soup.

WEDNESDAY.

=Breakfast.=--Cornmeal mush with hot milk.

=Dinner.=--Lima beans with carrots, potatoes and parsley.

=Supper.=--Yellow dock (raw or cooked) and egg toast with stewed prunes.

Cost of additional foods for Wednesday: Carrots 5 cents,--total 5 cents.

THURSDAY.

=Breakfast.=--Mashed turnips or carrots and toast with butter.

=Dinner.=--Lettuce salad with unleavened apple pancakes.

=Supper.=--Meat soup of lamb with rice and tomatoes. Toast with butter.

Cost of additional foods for Thursday: Shoulder or neck of mutton 15 cents, lettuce 5 cents,--total 20 cents.

REMARKS: Cut the meat in five pieces, cover with a little hot vinegar for half an hour, pour off; then add soup stock and keep in gelatine until Saturday.

FRIDAY.

=Breakfast.=--Cream of wheat porridge and butter.

=Dinner.=--Cooked spinach with fish and baked noodles.

=Supper.=--Strawberries with toast and scrambled eggs.

Cost of additional foods for Friday: Fish 15 cents, strawberries 10 cents,--total 25 cents.

Total expenditure for the week 85c.

SATURDAY.

=Breakfast.=--Left-over noodles with tomato sauce.

=Dinner.=--Raw cabbage salad with mayonnaise dressing and lamb in gelatine. Bread.

=Supper.=--Cream of tomato soup with fried bread and celery.

Cost of additional foods for Saturday: Cabbage 5 cents, celery 5 cents,--total 10 cents.

SUNDAY.

=Breakfast.=--Creamed boiled cabbage with stale bread or toast.

=Dinner.=--Fruit salad of apricots or peaches and lettuce with rolled rye and nuts (4 to 8 walnuts per person).

=Supper.=--Pancakes or cornmeal patties with fruit sauce.

Cost of additional foods for Sunday: Nuts 10 cents, fruit 10 cents, lettuce 5 cents,--total 25 cents.

MONDAY.

=Breakfast.=--Rice soup of buttermilk or milk with prunes.

=Dinner.=--Mixed boiled dinner of lima beans, carrots and potatoes.

=Supper.=--Egg toast or pancakes with fruit sauce.

Cost of additional foods for Monday: Skim-and buttermilk 10 cents, carrots 5 cents,--total 15 cents.

REMARKS: Use part of the milk for pancakes. Leave some for clabber milk.

TUESDAY.

=Breakfast.=--Stale bread with peanut-butter and apples.

=Dinner.=--Clabber milk with zwieback, doughnuts or pancakes (prepared with eggs).

=Supper.=--String beans and meat stew with dumplings.

Cost of additional foods for Tuesday: String beans 10 cents, meat 10 cents,--total 20 cents.

WEDNESDAY.

=Breakfast.=--Cherries with corn bread or egg toast.

=Dinner.=--Yellow dock on toast. Steamed rice pudding with fruit sauce.

=Supper.=--Raspberries and fresh milk with toasted bread.

Cost of additional foods for Wednesday: Cherries 10 cents, raspberries 10 cents, milk 10 cents,--total 30 cents.

THURSDAY.

=Breakfast.=--Left-over yellow dock and Roman meal cakes or bran muffins.

=Dinner.=--Julienne soup with fried bread. Apple rice with peanut sauce. Raw celery.

=Supper.=--Asparagus with French dressing or butter sauce and frankfurters or chipped beef and bread.

Cost of additional foods for Thursday: Asparagus 10 cents, meat 5 cents, celery 5 cents,--total 20 cents.

FRIDAY.

=Breakfast.=--Rolled wheat porridge with butter.

=Dinner.=--Baked noodles with tomato sauce and lettuce.

=Supper.=--Milk soup with black crusts.

Cost of additional foods for Friday: Lettuce 5 cents, skim-milk 5 cents,--total 10 cents.

Expenditure for staple foods $4.85 Total Expenditure for first week .85 Total Expenditure for second week 1.30 ---- Total $7.00

Staple Foods for Two Weeks. (Cost in Cents.) Stale whole rye and wheat bread 5 loaves .40 Roman meal 1 package .15 Cream of wheat 1 package .20 Rice 6 pounds .25 Potatoes 4 pounds .20 Raw tomatoes 3 pounds .10 Bacon ½■ pound .15 Green dried peas 2 pounds .10 Cow beans 2 pounds .10 Lentils 2 pounds .10 Corn meal 4 pounds .10 Salt 1 bag .05 Vinegar 1 pint .05 Lemon ½■ dozen .10 Cotton seed oil 1 quart .25 Olive Oil 1 bottle .25 Apples 6 pounds .25 Rolled rye 1 package .15 Rolled wheat 1 package .10 Corn starch 1 package .10 Butter 1 pound .20 Eggs 2 dozen .45 Peanut butter 1 jar .25 Baking powder 1 can .15 Radishes 2 bunches .05 Green onions 2 bunches .05 Walnuts 2 pounds .25 Lettuce 3 heads .05 Celery 1 bunch .05 Carrots 2 bunches .05 ---- $4.70

A few staple foods, such as coffee, bran and a few cereals, are supposed to be left over from the last two weeks.

Use peanut butter in place of butter.

SATURDAY.

=Breakfast.=--Green onions and radishes with bread and butter.

=Dinner.=--Tomato salad and lettuce. Creamed horse beans with parsley. Bread.

=Supper.=--Rice and tomato soup. Celery.

Cost of additional foods for Saturday: None.

SUNDAY.

=Breakfast.=--Mashed carrots. Lettuce salad and horse beans.

=Dinner.=--Apple and lettuce salad. Nuts (4 to 8 per person).

=Supper.=--Lemon pie with black malt coffee.

Cost of additional foods for Sunday: None.

MONDAY.

=Breakfast.=--Cream of wheat with butter.

=Dinner.=--Lamb or beef stew with dumplings. Celery.

=Supper.=--Green pea soup with fried bread or left-over dumplings.

Cost of additional foods for Monday: Meat 10 cents,--total 10 cents.

REMARKS: Prepare enough pea soup for the next day.

TUESDAY.

=Breakfast.=--Fruit salad of apricots, peaches or plums, and lettuce with rolled raw wheat or rye.

=Dinner.=--Pea roast or steamed bread pudding with tomato sauce. Celery.

=Supper.=--Fresh berries and toast with milk.

Cost of additional foods for Tuesday: Fruit 5 cents, lettuce 5 cents, celery 5 cents, berries 10 cents, milk 10 cents,--total 35 cents.

WEDNESDAY.

=Breakfast.=--Roman meal cakes with lettuce and syrup dressing.

=Dinner.=--Buttermilk soup with rice and raisins. Nuts (4 to 6 per person).

=Supper.=--Egg toast and lettuce with fruit sauce.

Cost of additional foods for Wednesday: Raisins 5 cents, buttermilk 5 cents,--total 10 cents.

THURSDAY.

=Breakfast.=--Water or muskmelon. Raw rolled rye mixed with chopped apples and lettuce.

=Dinner.=--Cherries and unleavened pancakes with syrup dressing.

=Supper.=--Green grapes and black bread with cream cheese.

Cost of additional foods for Thursday: Melon 10 cents, cherries 10 cents, grapes 5 cents, cheese 10 cents--total 35 cents.

REMARKS: Leave one-half of the cream cheese for Saturday.

FRIDAY.

=Breakfast.=--Rolled rye and wheat porridge with hot milk and raw cucumbers.

=Dinner.=--Cucumber salad. Green peas with dumplings and creamed fish.

=Supper.=--Bread soup (with buttermilk).

Cost of additional foods for Friday: Fresh milk 10 cents, buttermilk 10 cents, peas 5 cents, cucumbers 5 cents, fish 10 cents,--total 40 cents.

Total expenditure for the week $1.30

SATURDAY.

=Breakfast.=--Stale bread with cream cheese and left-over raw greens.

=Dinner.=--Meat croquettes (of soup meat) with creamed beets and bread.

=Supper.=--Rice and tomato soup with soup stock. Celery.

Cost of additional foods for Saturday: Soup bone 5 cents, tomatoes 10 cents, beets 5 cents, celery 5 cents,--total 25 cents.

SUNDAY.

=Breakfast.=--Salad of chopped apples and celery with mayonnaise dressing and raw rolled wheat or rye.

=Dinner.=--Cherry-or currant-or apple-rice. Nuts.

=Supper.=--Tomato salad and egg toast.

Cost of additional foods for Sunday: Fruit 5 cents,--total 5 cents.

MONDAY.

=Breakfast.=--Corn meal mush with hot milk.

=Dinner.=--Tomato salad. Stewed lentils with creamed onions.

=Supper.=--Lentil and tomato soup with toast or bread.

Cost of additional foods for Monday: Milk 10 cents,--total 10 cents.

REMARKS: Dilute the left-over lentils and tomatoes with water, add onions. Cook for 20 minutes, run through a colander, mix with flour and fat, add hot milk.

TUESDAY.

=Breakfast.=--Creamed potatoes with frankfurters and parsley.

=Dinner.=--Cherries and corn meal pudding with lemon sauce.

=Supper.=--Milk soup of rice with black crusts.

Cost of additional foods for Tuesday: Cherries 5 cents, frankfurters 5 cents, skim-milk 5 cents,--total 15 cents.

REMARKS: Use left-over corn meal for pudding; add 4 to 5 eggs.

WEDNESDAY.

=Breakfast.=--Raw cabbage salad with mayonnaise dressing and bread with butter.

=Dinner.=--Meat stew with dumplings and lettuce salad.

=Supper.=--Bran muffins and tomato puree. Boiled skim-milk.

Cost of additional foods for Wednesday: Meat 10 cents, lettuce 5 cents, cabbage 5 cents,--total 20 cents.

THURSDAY.

=Breakfast.=--Cream of wheat gems and lettuce with syrup dressing.

=Dinner.=--Mixed boiled dinner of string beans, potatoes and pears. Cornbread.

=Supper.=--Corn starch pudding with boiled hot or cold milk and black crusts.

Cost of additional foods for Thursday: Beans 5 cents, milk 10 cents, pears 5 cents,--total 20 cents.

FRIDAY.

=Breakfast.=--Rolled rye porridge with butter and syrup.

=Dinner.=--Bread dumplings or fritters with pea puree or stewed pears.

=Supper.=--Creamed cabbage with frankfurter and bread.

Cost of additional foods for Friday: Frankfurter 5 cents,--total 5 cents.

Expenditure for staple foods $4.70 Total Expenditure for first week 1.30 Total Expenditure for second week 1.00 ---- Total $7.00

HOW TO FEED A FAMILY OF FIVE ON $5.00 PER WEEK OR 14 CENTS PER PERSON PER DAY DURING SPRING AND SUMMER.

Buy about the same staple foods as suggested for the foregoing menus. Use less bread and cooked porridge or mushes. Buy more starchy fruits, such as bananas, stone fruits, melons and raw vegetables; combine them with toasted bread or raw cereal flakes. For those who eat two meals per day and have a late breakfast, it is better to combine fruits with nuts for breakfast in place of cereals. Use rich milk or cream with fruits for supper in place of those foods suggested in menus for supper. For other combinations study menus.

SUGGESTIVE MENUS DURING THANKSGIVING WEEK.

WEDNESDAY.

=Breakfast.=--Fried sweet potatoes with fried bacon and apple sauce.

=Dinner.=--Stuffed turkey neck with cranberry sauce.

=Supper.=--Tomato soup with fried bread.

THANKSGIVING.

=Breakfast.=--Creamed onions with bread and butter.

=Dinner.=--String bean salad with French dressing. Turkey with apple dressing, celery, cranberry compote. Plum pudding with sauce. Black coffee.

=Supper.=--Apple pie with black coffee.

FRIDAY.

=Breakfast.=--A fast or some fruit juice.

=Dinner.=--Plain water rice with turkey gravy.

=Supper.=--Green pea soup with fried bread.

SATURDAY.

=Breakfast.=--Roman meal cakes with cranberry sauce.

=Dinner.=--Brown flour soup from turkey bones. Left-over plum pudding.

=Supper.=--String bean salad. Baked squash with fried bacon.

REMARKS: Cut the turkey into pieces and preserve in gravy.

SUNDAY.

=Breakfast.=--Apple salad with lettuce and mayonnaise dressing. Bread.

=Dinner.=--Green pea soup. Mince pie and cheese.

=Supper.=--Fruit cake with coffee.

MONDAY.

=Breakfast.=--Codfish cakes with apple-or tomato-rice.

=Dinner.=--Boiled onions. Turkey with steamed potatoes and gravy. Celery.

=Supper.=--Squash or pumpkin pie with black coffee.

TUESDAY.

=Breakfast.=--Buckwheat groats with hot cream.

=Dinner.=--Turkey hash or salad with tomatoes and lettuce.

=Supper.=--Huckleberry soup with sago or dumplings.

RECIPES FOR MIXED BOILED DINNERS.

They are much appreciated in many foreign countries by people of moderate means. The housekeeper who does her own work can save much time by introducing a few of these menus at her table. The preparation of foods in this manner requires less water, it is more of a steaming process, and fewer dishes and utensils are needed.

Dishwashing becomes a burden in many a large household and the intelligent homekeeper studies economy in all directions.

I ask in advance that you try the recipes; lay aside prejudice against some of the good old-fashioned dishes, to which you are not accustomed, and stop wasting your time over new and fashionable recipes that ruin your health. Simplicity and knowledge are a great help for a low purse.

I.

Lima Beans with Carrots and Potatoes.

Soak one pound of lima beans in rain or soft water over night, cook for half an hour, add salt, and then add five good sized carrots cut to the size of the beans. Cook both for half an hour, then add four or five potatoes and cook all together until done. Thicken the broth with corn starch, add chopped parsley and butter. A tablespoon of vinegar and sugar may be added to the sauce if the flavor is desired. The carrots may be cooked by themselves; when done, add the water to the beans and potatoes, pour a little diluted vinegar over the carrots, let stand 20 minutes, drain off the vinegar and add the carrots to the beans and potatoes. This is preferable for people who dislike the sweet taste of the carrots. Serve with pork, bacon, frankfurters or without meat. Bread is not needed at this meal, as potatoes and carrots furnish sufficient carbohydrates. If bread is desired, it should be eaten in place of dessert with a little unsweetened black coffee or malt coffee.

II.

Small White or Brown Beans with Carrots and Potatoes.

Prepare the same as the foregoing. The time for cooking beans depends on the quality. The carrots should not be added until the beans are nearly done.

III.

Dried Green Peas with Carrots and Pork.

Prepare the same as the foregoing. Young green peas or string beans may be used in place of dried ones. The latter are excellent during the summer in combination, with salted pickled herring or creamed chipped beef.

IV.

Green Dried Peas with Dumplings.

See recipe for bread or flour dumplings. Cook the dumplings in salted water and serve with the peas in place of meat or prepare a pea soup and boil the dumplings in the soup. This makes a perfect meal for dinner.

Use one-fourth to one-half a cup of dried peas per person, according to size and age of the individual. Green fresh peas may be substituted in the summer. Fried bacon is a good addition.

V.

Dumplings with Potatoes and Prunes.

Steam the potatoes. Prepare some nutritious dumplings from flour or bread with eggs. Heat some butter, bacon fat or oil, add finely chopped onions, fry until brown, remove from the fire and add two tablespoons of syrup and some lemon juice or vinegar. Pour the potatoes and dumplings on a dish, mix with stewed cold or warm prunes, pour the syrup sauce over it and serve. Serve with lettuce. The syrup sauce can be thickened with flour and strengthened with the water in which the dumplings have been cooked; the prune juice can be added in place of the syrup. Serve with fried bacon. Good during the summer.

VI.

Potatoes, Macaroni and Prunes.

Cook the macaroni until very tender, drain off the water, combine and serve in same manner as the foregoing.

VII.

Fried Dumplings.

Cut left-over dumplings into thin slices, fry in hot fat or butter until brown. Flavor with onions if desired.

PART FOUR

CHAPTER I.

DISEASE.

Disease is that condition of the body where there is any departure from the normal, in function, or structure. It may be local or general, and may tend to recovery, death or life-long suffering.

Many so-called forms of dyspepsia are brought about by improper eating, or by eating when not hungry or when tired. In such cases, a regulated life and the right selection, combination and preparation of foods is the only means to correct it.

ULCERATION OF STOMACH AND INTESTINE.

Causes: After effects from acute diseases, worry, envy, excesses of eating or drinking, bony displacements, anemia and overwork. The patient should consult a physician at once. If certain areas of the glandular structure of stomach or intestine have been destroyed once, the normal structure cannot be restored; but with good care and proper dietetic measures great improvement can take place. Excess of starchy foods is always harmful. Particles of food not well masticated can cause much disturbance. The presence of fats in large amounts or wrongly combined with other foods will also retard digestion; they cause the pyloric orifice to contract more, and leave the food contents in the stomach for a long time, and in this way cause fermentation and putrefaction.

Dyspepsia and indigestion are the beginnings of a disordered metabolism and if neglected the results are: Nervous prostration, insanity, consumption, pelvic disorders, difficult child-birth, weak offspring, different forms of tumors and cancers and a multitude of fashionable and epidemic diseases.

CONSTIPATION.

The recognized rule is that the bowels should be evacuated once per day. Nevertheless, there are a number of people whose bowels act only every second or third day, and whose health is not impaired thereby. Healthy people who live on natural foods, such as raw fruits, nuts and grains, or on simple cooked foods with a moderate amount of meat, as a rule will not find it necessary to resort to artificial means for evacuation of the bowels.

People, whose diet consists mainly of meats, cooked vegetables and potatoes mixed with fermentable substances, or those who mix meat with milk and sweets or soft puddings will find it absolutely necessary to have a daily evacuation of the bowels, in order to retain perfect health.

CHRONIC CONSTIPATION.

Different habits of diet have a great effect upon evacuations. People who suffer from chronic constipation without any particular ailment or disease may often be greatly benefited by adding a greater amount of fruits or vegetables to their diet. Others find it necessary to discard cooked fruits for a while and take oily substances. Some people are constipated from insufficient protein elements in their food. The original cause may have been mechanical obstruction. Morbid anatomy and morbid physiology go hand in hand. Therefore, if proper hygiene and diet does not correct the condition, the patient should consult a physician for special treatment.

MALARIA.

Malaria is a germ disease, but like many other germ diseases, the primary cause is lowered resistance, caused by poisoned air and adulterated food stuffs. Protection against adulterated food stuffs depends upon enforcement of pure-food laws, and the training of every housekeeper in the art of domestic science. Impure milk, whether poisoned by the milkmen or handled carelessly by the housekeeper, cannot be turned into good blood. The same is true of other food stuffs.

Dry, pure air is absolutely necessary for the patient who suffers with malaria. Dwelling places near which are stagnant pools, rain barrels, marsh land or stores where decayed fruits and vegetables are housed, are dangerous to people who are afflicted with malaria or any other germ disease. Mosquitoes are held responsible for both malaria and yellow fever. They breed in warm weather, wherever stagnant water is found. To prevent a disease that is spread by animal or vegetable parasites we must direct our effort against the breeding places of these disease carriers. Coal oil, poured upon the surface of stagnant water on streets, or near our homes, is a great help in preventing the multiplication of mosquitoes. Screens on dwelling houses, dry basements, plenty of sunshine in the home and the prevention of accumulation of vegetable refuse can do much toward protection from these parasites.

People who are afflicted with partial congestion of the portal circulation have stagnant and poisoned blood, and are more liable to contract malaria than those whose liver is in good working order. Many people are under the impression that they have liver trouble if they put more work upon this organ than it is able to do. Overtaxing of any part of the body will finally result in congestion and disease.

If mechanical obstructions are responsible for sluggish conditions of the liver, they should be remedied by anatomical and physiological adjustment. Deep breathing is of the greatest importance in all diseases affecting the abdominal organs. Fresh air at night is as important as during the day. During rainy weather have a fire going during the night in order to keep the air dry. Protect the body with warmer clothing after sunset, and wear light woolen underwear if necessary to avoid chills during sleep.

The diet should be light and nutritious. Avoid all rich condiments, spices, soft puddings containing milk and eggs, yeast breads and cakes. Some cases should avoid milk, cheese, shell-fish and other foods rich in protein.

THE FOLLOWING SUGGESTIONS MAY BE HELPFUL TO INVALIDS WHO SUFFER FROM CHRONIC AFFECTIONS OF THE LIVER AND INTESTINAL INDIGESTION.

1. Spend at least four hours per day out of doors.

2. Take short walks before and after dinner and before and after supper. Take deep breathing exercises by open windows before breakfast, and exercise the lower limbs while in bed.

3. Have breakfast at 9 a. m. and supper between 4 and 5 p. m.

4. Never work or eat when the hands and feet are cold.

5. Relax and breathe deeply with face down for 20 minutes, three times per day before meals.

6. During damp or rainy weather rest more, eat more greens, citrus fruits and fatty foods, and little or none of those foods which are rich in protein, such as cheese, whites of eggs, lean meats, nuts, beans, canned corn and milk foods, and select protein foods for the noon meal in the form of green pea or lentil soup, with or without tomatoes, or fat cold pork, fish or bacon in combination with apples, mashed beets, carrots or yellow turnips with lemon, hard yolks of eggs and fried bacon. Rice with tomato sauce and cold fat meat is also good. Black stale bread is best.

7. For breakfast use fats in the form of mayonnaise dressing with raw apples and tomatoes and plenty of onions, also fat meat if desired, and corn meal mush with eggs and cranberry sauce and celery; or the above mentioned green leaf vegetables. Celery

roots, raw or cooked, with lemon and toasted bread and butter or fried bacon is also good. Use raw carrots, cranberries and beets with greens and French dressing. Raw cabbage is also good.

8. For supper select your food according to your appetite. If you are warm, active and energetic, take some raw fresh milk with zwieback and tomato or cranberry juice, or suck the juice of one-half or one-fourth of a lemon or grapefruit with it, white and yellow skin and all, expectorate the residue. Bran tea, barley or oatmeal water with one-fourth sterilized cream is good. If you are cold and chilly eat a plate of warm soup made of tomatoes or plums, huckleberries, string beans or asparagus (treated with lemon), or potato soup, or eat green cooked leaf vegetables with lemon and fried bacon, toasted or puffed wheat, and butter.

9. During the dry, frosty season, when the sun is bright during the middle of the day, eat a moderate amount of those foods forbidden under No. 6, combine them rightly, and take walks in the sunshine after dinner.

10. Mornings and evenings eat about the same foods as suggested in the foregoing.

11. Dress the body according to the changes of temperature.

12. Avoid over-heated rooms, and stay in bed until the sun rises, if necessary.

13. Keep the bowels in good order by enemas.

14. Black malt coffee prepared with a few whole or crushed coffee beans is of medicinal value if taken in small quantities after meals, especially after the noon meal; it acts as a tonic to the liver. Raw cranberries may be substituted if desired.

The above mentioned suggestions are for extreme cases of liver degeneration. They also apply to many chronic, so-called incurable diseases where the protein and starches of the diet should be limited in quantity to the minimum, compatible with the requirements of the individual.

There are cases of liver trouble where there is no interference with the glycogenic and oxidizing action of the liver, and where an entirely different diet is required. Therefore, no patient should attempt to treat a disease by a book, without having his case diagnosed by a physician and receiving advice as to the special diet required.

TUBERCULOSIS.

It is one of the most fatal diseases that affects men and animals. It is due to a germ called the bacillus of tuberculosis. This germ, however, is not the primary cause for the development of the disease. Wrong environment, unclean air and food are the causes that multiply these germs. Hereditary weaknesses play an important part, but the disease itself is never inherited. Lowered vitality, infection through milk and meat, and careless spitting are in a large measure responsible.

Children of parents who suffer from tuberculosis may grow up into healthy and strong individuals, if the proper conditions are furnished. Tendencies to disease are universally manifest in the weaker structures, and this weaker resisting power is the exact measure of the power inherent in heredity.

Tuberculosis may affect the lungs or manifest itself in different parts of the body, and is known under the following names: Potts disease or curvature of the spine; hip joint disease, when it affects the hip joint; white swelling or knee joint disease; ankle joint disease; lupus or skin disease; scrofula, when it affects the glands of the neck; tuberculous ulceration, when it affects the inside of the intestine; tuberculous peritonitis, when it affects the outside of the intestine; and consumption, when the lungs are involved.

PREVENTION OF TUBERCULOSIS.

The House We Live In.

Sunlight is the best known disinfectant. The direct rays of the sun destroy tubercular germs and the majority of other micro-organisms. Plants cannot grow without sunshine. Human beings cannot enjoy health in dark dwelling places, without sunlight. The houses we live in should contain a large number of windows and glass doors, so as to permit all rooms to be permeated with sunlight. It is a pity that modern houses, with all their conveniences and sanitary arrangements, have so little provision for proper sterilization by sunlight.

Many new modern houses are provided with a lot of unnecessary closet room, pantries and double stairways, halls and other accessories, which shut up impure air and prevent proper ventilation. Instead of living in large, luxurious houses, our health and

comfort could be greatly improved by the investment of more space in artistically constructed gardens. Smaller houses, long and narrow in form, or wide and short, according to the location and size of the lot, could be daily disinfected and sterilized from cellar to attic by the rays of the glorious sun. A building of this kind may consist of two, four, eight, ten or more rooms, with one or three floors, and can offer comfort for one family, or be divided into apartments or flats. A house should be built on porous ground.

A lower floor, with parlor and spare bedrooms, is more easily ventilated and kept clean than a high basement with poor flooring, and no provision for proper airing or the admission of sunlight.

The mother of a family who has to do her own work in a two-story house could save much time and strength by having her kitchen and dining room on the upper floor, with hall and stairway and glass door in the center of the house, which would enable her to attend to the door from above. A house so constructed could easily be provided with porches for sleeping, and a place for the children to play during the morning hours, and in this way relieve the mother of many unnecessary steps.

Large, beautiful gardens call for work which is mixed with brains, while large houses with fashionable accessories call for slavery and compel one woman to become the servant of another woman.

All human beings are born with a pair of arms, which by gradual development enable them to care for their bodies in matters of feeding, dressing, hygiene and comforts. Assistants in the home are required for the child, the sick and the helpless.

Modern inventions relieve us partly of house-cleaning and laundry work, and modern methods of simple feeding and luxurious airing will relieve us from solving the servant problem and prevent diseases that are created by wrong living.

TREATMENT OF TUBERCULOSIS.

Clinical experience with hygiene and diet have proved that they are the most important factors in the treatment of disease.

A certain class of patients who are in the early stages of this disease may be benefited by a liberal diet, but the larger percentage of sufferers really have indigestion and can only gain benefit by cutting down their diet and by living upon plain, non-stimulating food. The amount of carbo-hydrate foods should be decreased and the amount of fats increased. Olive oil in combination with raw vegetables, acid fruits and raw eggs and fat meats should be given daily. They are best taken for breakfast. The heavier protein foods should be eaten at the noon meal in combination with a small amount of cereals and raw greens. The evening meal should consist of broths with egg, cooked green vegetables, toast and bacon, or of milk foods. If extra milk is required it should be given with a keen appetite. Food eaten without relish cannot be properly oxidized and assimilated.

People who are compelled to work while sick should take some extra milk between 10 and 12 a. m. and during the afternoon. Milk may be taken raw or boiled, according to the individual requirements. The bowels should be kept in order by enemas and laxative foods.

RICKETS.

This is a condition where there is interference with the nutrition of the bones. The bones, like other parts of the body, are injured by lack of nourishment; they become soft and yielding like wax, and are drawn by the muscles into deformity. The animal matter which enters into the composition of the skeleton is in great excess, and the earthy (or mineral matter) is deficient in proportion. Causes for such conditions are: Lack of lime and minerals in the food, before or after birth; impure or inferior milk; fermenting foods; excess of starchy foods, sweets and meats; insufficient greens, legumes and nut-foods in the mother’s food, and overwork of the mother before or after birth of the child; damp and impure air and unhealthy dwellings. The first symptoms of this disease or a tendency to it can sometimes be detected in a child during the first year by soft and flabby muscles, excess of fat, difficulty and backwardness of learning to walk, and in cutting teeth, extremely narrow chest, continual digestive disturbances with constipation or greenish looking evacuations, and catarrh of the bowels. Softening of the bones of the head is often present.

The prevention and treatment of this disease demands careful regulation of the diet, sufficient sleep, pure air, dry, sunny dwellings, warm baths, massage and salt rubs. If the child perspires much on the upper part of the body during sleep, avoid feather pillows and keep the lower limbs warm by artificial heat if necessary. Avoid pressure on the head by placing a narrow pillow about two inches in width under the neck, and no pillow under the head. Keep the child in the lying position as much as possible. Do not carry it on the arm except when necessary, and never force it to stand or walk against its own will.

The diet should consist of milk and cream with well cooked strained pearl barley and steel cut oats or bran, a moderate amount of toast, calf's-foot jelly, eggs, strained legumes and fat meats. Raw greens, fruits and nuts should be given as soon as the child is able to digest them without difficulty. Always select the food in the right combination and never allow excesses of any kind. The bowels must be kept regular by enemas.

OBESITY.

Obesity is a constitutional disease, due to excess of food in general or to excess of wrong food and interference with the nerve supply controlling the oxidation processes.

Thousands of people who suffer from this "fat habit" could cure themselves by proper attention to hygiene and diet. A normal individual who lives right, thinks right and is engaged in useful work, does not need to carry useless fat around with him.

Do not take the advice of a friend who promises relief with dangerous drugs and salves, or excessive steam-baths and violent exercises. A diet suitable in quality and quantity to the particular constitution, useful activity, alternated with sufficient rest and recreation, and plenty of sunlight and dry, fresh air, are the only means to bring permanent results. A change of occupation is necessary at times. The dry diet, consisting of the necessary amount of proteins, with a large amount of raw greens or fruits and fats, and abstinence from tea and coffee and foods which are rich in starch and sugar, will bring relief to the majority of people who have a tendency to grow stout.

There are special conditions which require special treatment, such as tonic baths, massage, sun-baths, osteopathic treatments and special prescribed diets and exercises which cannot be discussed here.

CHAPTER II.

CARE AND FEEDING OF CONVALESCENTS.

Convalescence depends much upon the proper food. Fevers require that the patient's strength should be kept up. If the body has been overfed on certain articles, these must be stopped, and those elements which are needed must be administered in the form of food, water, air and so on. The fever is nature's method of throwing off disease,--and if properly guided it does not become dangerous. A physician should be sent for at once. The diet prescribed for the patient and the directions in regard to quantity, temperature and time of administration should be carried out in every detail, just like other directions in regard to nursing. Many a patient has been seriously injured or even killed through the administration of foods which were forbidden by the doctor. At times there is a special desire for a particular kind of food. It may be an indication that the system requires it, and such craving should always be reported to the doctor, and if possible the physician will suggest such a food or some substitute which will answer the purpose.

The temperature of the food should be tested before serving. Blood warm is generally the best. The tray should not be loaded with a variety of foods. The patient should not be tempted with food unless forced feeding is indicated.

If the tongue is coated, give a little water with lemon juice before breakfast, especially if milk foods are to be eaten. If the appetite is not keen, do not take milk foods for breakfast.

VOMITING.

If vomiting occurs or is continued for any length of time, it may be checked by giving cold weak tea or black coffee at frequent intervals, or a few drops of brandy in a tablespoonful of ice water. In many cases it is better for the patient to have his breakfast in bed for some time after recovery, especially if the exertion of dressing is tiresome or the temperature of the room is unsuited to the patient's condition. A mild warm room is preferable to an overheated one.

DIET.

Diet for the sick may be classified as liquid, semi-liquid and solid foods. A liquid diet is generally given only during acute illness or after operations. The kind of food, as well as the amount and intervals at which it should be given, are usually prescribed by the attending physician. Therefore, only a few suggestions are given.

If nourishment by enema is necessary, predigested substances are the best; peptonized milk and malt extracts or well prepared, strained gruels of bran and oats, or of bran alone, to which one to two teaspoonsful of brandy have been added. Black cereal coffee or weak black coffee are often excellent where stimulation is desired. The amount should be from one to three ounces at a time, and the temperature should be luke warm. It must be injected very slowly.

If the patient is of a nervous temperament, or suffers from irritability of the stomach, he should have as little animal food as possible, especially for breakfast. As a rule a well prepared water gruel satisfies the demands of the body until the noon hour. It acts as a sedative and rests the whole body, and in this way more nervous energy can be expended for digestion at the noon meal.

There are some exceptions; for example, if a patient has had a restless night and is exhausted, he may have a cupful of freshly prepared whey or bran-tea with milk or cream before his breakfast. As a rule such conditions should not appear during convalescence, and may be prevented by intelligent nursing and avoidance of unnecessary company.

The greatest care should be taken not to allow a patient to eat rapidly or to take large quantities at one time, and also to avoid foods which produce fermentation.

SUGGESTIVE MENUS.

1. Breakfast.

A cup of whey with or without lemon, and albumen water.

10 to 11 A. M.

Five to ten ounces of milk, diluted with gruel or tea.

Dinner.

Gelatine prepared from barley, rice, bran or legumes and a little zwieback.

3 to 4 P. M.

Cocoa or milk (5 to 10 ounces) with zwieback.

Supper.

Malt coffee with hot cream and milk-sugar and zwieback.

If food is required at 10 p. m. or during the night, whey, blackberry juice, broth, apple water, orange juice, egg-wine, tea, coffee or lemonade may be given if allowed.

2. Breakfast.

Water gruel prepared from barley or bran, rye or steel cut oats, cream of wheat or rice. Malt coffee with triscuit.

10 to 11 A. M.

Broth with the yolk of an egg or fresh milk with crackers or crusts.

Dinner.

Gelatine of wheat or toast with sterilized cream and zwieback or ryenuts.

3 to 4 P. M.

Milk, coffee, cocoa or eggnog with zwieback or crackers.

Supper.

Chicken or clam broth with one or two tablespoonsful of cream, ryenuts or zwieback.

Allow the patient to return to simple solid foods gradually. If he tires easily of one thing, as much variety as possible should be introduced into the diet, but as a rule no more than three or four articles should be served at one meal.

3. Breakfast.

Onion gruel, bread gruel, codfish gruel or cornmeal gruel.

10 to 11 A. M.

Milk or barley water with cream and toast.

Dinner.

Toast with poached egg. Asparagus with lemon or cream dressing.

3 to 4 P. M.

Malt coffee, black or with cream, zwieback or unleavened biscuits with butter.

Supper.

Strained pea soup or cream of tomato soup with zwieback or raw celery.

4. Breakfast.

Bread soup prepared with prunes or imported root beer. (Excellent for constipation.)

10 to 11 A. M.

Milk or veal broth with the yolk of an egg, and crusts or zwieback.

Dinner.

Puree of dried green peas, beachnut bacon, zwieback, raw celery.

3 to 4 P. M.

Cold water or malt coffee.

Supper.

Beer or wine gruel or boiled custard with zwieback.

5. Breakfast.

Gruel of Cook’s flaked rice or shredded wheat with butter, or hot sterilized cream.

10 to 11 A. M.

Whey or broth.

Dinner.

Spinach on toast, two eggs, beachnut bacon.

3 to 4 P. M.

Raw bran, oatmeal water, almond milk or hot or cold water.

Supper.

Sago gruel prepared with blackberries, apples or huckleberries (strained), and zwieback with butter.

6. Breakfast.

Cereal gruel prepared with two-thirds water and one-third milk or one-fifth cream.

10 to 11 A. M.

Water, whey or tea of beans, peas, lentils or bran.

Dinner.

A raw or baked apple with fish. Lettuce with mayonnaise dressing.

3 to 4 P. M.

Water, bran water or milk.

Supper.

Soup of carrots, peas or asparagus with toast.

7. Breakfast.

Cereal coffee, bran or legume tea, one slice of whole wheat toast, or stale bread. One egg.

10 to 11 A. M.

Vegetable water or whey.

Dinner.

Green pea soup with raw celery. Raw oysters and crackers with butter.

3 to 4 P. M.

Almond milk, bran water or cold or hot water.

Supper.

Baked apple with sterilized cream. Cream of celery soup with toast.

8. Breakfast.

Milk or water gruel with crusts.

Dinner.

Apple salad and lettuce with sweet breads. Orange juice.

Supper.

Cream of tomato soup or clam broth with toast and raw celery.

9. Breakfast.

Melon. Codfish cakes, raw apples or ambrosia.

Dinner.

Pea or lentil soup. Squab on toast with tomato or apple salad and lettuce.

Supper.

Cream toast or fruit soup or whey soup.

10. Breakfast.

Lettuce or watercress or celery with or without dressing. Baked potatoes, one or two eggs and beachnut bacon.

Dinner.

Broth with egg. Cream cheese with apple salad, black toast, olives.

Supper.

String beans, creamed chipped beef, crackers or triscuit.

11. Breakfast.

Green grapes, banana salad with lettuce and French dressing.

Dinner.

Three ounces of strained tomato juice, young peas with bacon or white fish, triscuit with butter and black cereal coffee.

Supper.

Sliced pineapple with gelatine and cream. Black toast.

12. Breakfast.

Gluten gruel, cream of wheat, or whey gruel.

Dinner.

Beefsteak with egg and spinach. Toast with butter.

Supper.

Milk or fruit soup or green cooked vegetables with bacon.

13. Breakfast.

Asparagus with French or cream dressing, chipped beef or boiled codfish with one or two tablespoonsful of raw wheat or rye flakes.

Dinner.

Strained tomato juice with buttered toast, or a piece of cucumber. Lamb chops with sprouts and the yolk of an egg.

Supper.

Cook’s flaked rice gruel with cream or butter and the yolk of an egg.

14. Breakfast.

Lettuce, creamed potatoes with parsley and boiled ham.

Dinner.

Tomato and lettuce salad with dressing. Scrambled eggs with string beans and bacon.

Supper.

Baked apples in gelatine with cold sterilized cream and unsweetened graham crackers.

15. Breakfast.

Fruit salad of peaches or apricots with almond cream and grapenuts or ryenuts.

Dinner.

Boiled beef or chicken with mushroom sauce and rice.

Supper.

Pea soup with buttered toast. Raw celery.

16. Breakfast.

Lettuce, egg toast with cranberry or apricot sauce.

Dinner.

Tomato soup. Lima beans with the yolk of an egg and lemon. Raw celery and parsley.

Supper.

Green grapes and black toast with butter or fruit pudding with sterilized hot or cold cream.

ADDITIONAL MENUS.

I.--Light Rice with Egg and Soda Crackers--233 Calories.

Wash two tablespoonsful of rice, boil rapidly in one pint of water with a little salt until the grains burst. Then boil slowly in the oven or on the stove (uncovered) until the rice is dry. Remove from the fire and add one teaspoonful of butter, the yolk of one egg and a few drops of lemon juice. Serve plain with two soda crackers or one small round zwieback.

Calories. Rice 2 tablespoons 100 Yolk of egg 1 48 Butter 1 teaspoon 35 Crackers 2 50 ---- 233

II.--Light Rice with Egg and Cranberry Sauce--263 Calories.

Prepare the same as No. I. Pour two tablespoonsful of cranberry sauce over the rice.

Cranberry Sauce, Sterilized--190 Calories.

Put one cup of cranberries into a pint jar, add two and one-half tablespoonsful of sugar and sufficient water to fill the jar; screw tight and cook in a water bath for 40 minutes or longer. Let cool and run through a colander.

III.--A Large Glass of Mixed Milk and Cream with Cranberry or Tomato Toast--525 Calories.

Heat two small round or one long zwieback and soften with two tablespoonsful of tomato or cranberry sauce. Serve on a plate and drink the milk with it.

Calories. Milk 8 ounces 165 Cream 4 ounces 230 Zwieback 2 small 100 Fruit Juice 2 tablespoons 30 ---- 525

IV.--Cream Toast of Whole Wheat Bread or Shredded Wheat--390 Calories.

Dissolve one tablespoonful of milk sugar in one-half or three-fourths cup of boiling water and pour over one slice of whole wheat bread or biscuit. Let stand a minute, then add four ounces of hot cream, and serve.

Calories. Cream 4 ounces 230 Biscuit 1 ounce 100 Milk Sugar 1 tablespoon 60 ---- 390

V.--Cornmeal with Egg and Cranberry Sauce--271 Calories.

Cook three tablespoonsful of cornmeal in one pint of water with a little salt, for 30 or 40 minutes.

Remove from the fire. Then add one teaspoonful of butter, the yolk of one egg and a few drops of lemon. Pour on a soup plate and serve with two tablespoonsful of cranberry sauce and one soda cracker or two black crusts.

Calories. Cornmeal 3 tablespoons 108 Yolk of egg 1 48 Butter 1 teaspoon 35 Crackers or Crusts 2 50 Cranberry Sauce 2 tablespoons 30 ---- 271

VI.--Apple Soup No. 1, with Two Black Crusts--440 Calories.

Heat a tablespoonful of olive oil and one of butter, mix with a tablespoonful of white flour, gradually add one pint of boiling water and stir.

When done, wash and grate one red Oregon apple with the skin. Add the grated apple to the soup, also a pinch of salt, a teaspoonful of sugar and a stick of cinnamon. Let all boil for about 10 minutes. Remove from the fire, add another teaspoonful of butter and a few drops of lemon; mix well, pour on a soup plate and serve with two crusts.

If the stomach is very delicate, the soup must be strained.

Calories. Apple 1 large 100 Flour 1 tablespoon 30 Olive Oil 1 tablespoon 100 Butter 1 tablespoon 105 Butter 1 teaspoon 35 Sugar 1 teaspoon 20 Crusts 2 50 ---- 440

VII.--Apple Soup No. 2, with Black Crusts--535 Calories.

Prepare as the foregoing. Add one-half cup of hot cream before serving; mix well. Omit the extra teaspoonful of butter, oil and lemon.

VIII.--Apple Soup No. 3, with Black Crust--488 Calories.

Prepare as No. 1. When done, dilute the yolk of one egg with a tablespoonful of water on a soup plate, stir well and gradually add to the soup, also add a teaspoonful of butter and a few drops of lemon.

IX.--Apple Soup No. 4, with Black Crusts--515 Calories.

Prepare as No. 2, omitting the sugar. This is good for diabetic patients.

X.--Apple Soup No. 5, with Black Crusts--468 Calories.

Prepare as No. 3, omitting the sugar. This is also good for diabetic patients.

XI.--Veal Soup with Sago. Zwieback with Butter--478 Calories.

Wash and soak three tablespoonsful of sago in one-half a cup of cold or warm water for several hours. Then boil it in one cup of water with a little salt. When the sago becomes too thick, add one cup of veal stock. Let it all boil together until the sago is done. Then remove from the fire, add a teaspoonful of butter and combine with the yolk of egg as directed for Apple Soup No. 2; also add a few drops of lemon. If flavoring is desired, boil a finely cut carrot and some parsley in the water before the sago is added. Remove the vegetables before serving. Celery is also good for flavoring. Onion does not combine well with sago. A great variety of vegetables in soup is not good for patients.

Use different ones each time, and the patient will relish it better.

Calories. Sago 3 tablespoons 90 Broth 1 cup 100 Butter 1 teaspoon 35 Yolk of egg 1 48 Zwieback 2 small 100 Butter 1 tablespoonful 105 ---- 478

XII.--Veal Soup with Cream. Crusts or Zwieback--453 Calories.

Prepare like the foregoing, omitting the lemon, butter and egg, and using three ounces of hot cream.

XIII.--Veal Soup with Green Peas and Zwieback.

Soak one-fourth of a cup of dry green peas in soft water over night. Boil them in about one pint of water until tender. Then add one cup of veal stock and more water if the peas are dry. Let all boil for one-half an hour longer, then strain.

If the soup is for very young children or invalids, do not press much of the pulp through. Put one zwieback on a soup plate, pour some of the soup over it, then add one or two ounces of hot cream and serve.

The broth may be mixed with the cream and served in a cup, and the zwieback eaten with it.

XIV.--Cream of Celery Soup No. 1--293 Calories.

Wash the celery stalks, scrape and cut into one-inch pieces. Boil in a very little water, with a pinch of salt. When tender, put the celery into one cup and the water into another cup. Squeeze the juice of one-half lemon on the celery stalks and let stand for 10 or 15 minutes. Heat a tablespoonful of butter and mix with a tablespoonful of mixed flour, and add the hot celery water. If there is not sufficient fluid, add more boiling water. When done, remove from the fire, add another teaspoonful of butter, then add the celery; mix well.

If the lemon makes it too sour, pour some boiling water over the celery, and let it drain through a colander. When ready to serve, combine the soup with the yolk of an egg, as directed in Apple Soup No. 3.

If vegetables cause fermentation, they are less liable to do so if treated with acids as directed above.

Calories. Celery 3 stalks 25 Butter 1 tablespoonful 100 Mixed Flour 1 tablespoonful 35 Yolk of Egg 1 48 Butter 1 teaspoon 85 ---- 293

XV.--Cream of Celery Soup No. 2--343 Calories.

Prepare and finish like the foregoing. Add one-half cup of beef, mutton or veal broth in place of hot water.

XVI.--Cream of Celery Soup No. 3, with Two Black Crusts. 436 Calories.

Prepare like No. 1, omitting lemon, egg and extra butter, and using three ounces of hot cream instead.

XVII.--Cream of Celery Soup No. 4, with Two Black Crusts.

Cook the celery as directed in No. 1. Add two teaspoonsful of cornstarch with water, and three ounces of hot cream.

XVIII.--Cream of Asparagus Soup with Black Crusts.

Prepare in the same manner as cream of celery soup, in four different ways.

XIX.--String Bean Soup, with or without Zwieback.

Select young, tender string beans, wash, trim and shred fine or break into one-half inch pieces. Cook in a very little water. Finish like Cream of Celery Soup, with or without lemon, egg or cream.

Add plenty of chopped parsley just before removing from the fire. This soup is very purifying to the liver and intestines, but should not be given to fever patients.

XX.--Cream of Cauliflower Soup with Black Crusts.

Prepare the same as Cream of Celery Soup. The use of lemon is important for people who suffer with gas and flatulent dyspepsia.

XXI.--Whey Gruel No. 1, with Zwieback.

Heat one and one-half cupsful of sweet or slightly sour whey to the boiling point. Melt a tablespoonful of butter, mix with a tablespoonful of mixed flour and add the hot whey gradually. Boil a few minutes. Remove from the fire, add the yolk of an egg and a few drops of lemon juice. If sour whey is used, add a tablespoonful of cane-sugar while it boils, or mix the gruel with a few soaked or stewed prunes or with dried currants. Add cream in place of egg and butter, if desired.

XXII.--Whey Gruel for Two Persons--503 Calories.

Wash one-fourth of a cupful or four tablespoonsful of sago several times with cold and warm water until the water becomes clear, then soak in one-half cup of cold or warm water for several hours over night. Bring two cups of whey to a boil with the peeling of

one-half a lemon or a piece of cinnamon bark. Stir in the sago, let boil 20 minutes, and add one-fourth teaspoonful of salt. Remove from the fire and add a teaspoonful of butter, the yolk of an egg diluted with a tablespoonful of cold water, and a few drops of lemon, or leave out the egg, butter and lemon, and add three ounces of hot cream. Mix well, pour on soup plates and serve with soda crackers or zwieback, or one-half of a raw red Oregon apple. One tablespoonful of sugar may be added if allowed. Sour whey may be used instead of sweet whey.

Calories. Sago ½■ cup 120 Whey 2 cups 200 Butter 1 teaspoon 35 Yolk of egg 1 48 Zwieback 2 100 ---- 503

XXIII.--Cornstarch Gruel with Whey.

Dissolve two tablespoonsful of cornstarch in a little cold water. Add one cup of water to a pint of whey, heat and stir in the cornstarch and boil 10 to 15 minutes. Finish the same as sago gruel. Rice flour, arrowroot, white flour or mixed flour may be used instead.

TABLE OF COMMONLY USED FOODS, GIVING CALORIC VALUE.

Almonds, 10 large 100 Apples, 1 medium 92 Bacon, 1 pound 2260 Broth, 1 cup 100 Bananas, 1 large 100 Barley, 1 tablespoon, raw 90 Beans, dried, ½■ cup, raw 300 Beefsteak, ½■ pound (round) 160 Bran, 1 cup 220 Butter, 1 tablespoon 105 Blue Fish, 1 pound 400 Carrots, 1 large 50 Celery, 12 stalks 100 Codfish, 1 pound 400 Cornmeal, 1 tablespoon 36 Crackers, 1 Uneeda 25 Cheese, 1 pound American 1800 Cream, ½■ cup from separator 230 Cucumbers, 1 large 40 Currants, 1 cup (dried) 700 Dates, 10 260 Eggs, 1 whole 60 Eggs, 1 yolk 48 Eggs, 1 white 12 Figs, 10 large white 600 Rice-flour, 1 tablespoon 55 Wheat-flour, 1 tablespoon 30 Mixed flour, 1 tablespoon 35 Cornstarch, 1 tablespoon 40 Gelatine, 1 tablespoon 80 Greens, 1 cup 40 Grapenuts, 1 tablespoon 30 Honey, 1 tablespoon 100 Kumyss, 8 ounces 100 Lamb chops, 1 small 100 Lemon, 1 whole 16 Lettuce, 1 head 40 Macaroni, 1 cup (raw) 300 Milk, 8 ounces 165 Oats, rolled, 1 cup (raw) 300 Oats, steel cut, 1 cup (raw) 900 Orange, 1 large 100 Oil, 1 tablespoon 100 Peanuts, 15 100 Peaches, 1 50 Peas, ½■ pound (dried) 350 Peas, green, 1 cup 150 Prunes, 5 (dried) 100 Potatoes, 1 large 100 Raisins, 10 large 100 Raspberries, 1 cup 60 Rice, 1 tablespoon 50 Syrup, 1 tablespoon 50 Sugar, 1 tablespoon 60 Tomatoes, 1 large 50 Walnuts, 8 100 Wheat, rolled, 1 cup (raw) 250 Whey, 1 cup 100

PART FOUR

APPENDIX.

MENTAL HYGIENE AND DIET.

Proper growth and activity of the brain and nervous system are promoted by a healthy flow of blood. Pure air and sufficient protein food properly combined and proportioned with carbo-hydrate and fatty foods, rich in phosphates and minerals, are essential. Choose more of the lighter form of protein and starchy foods, as fish, eggs, almonds, green peas, bacon, a moderate amount of lamb and beef, rice, sago, wheat, and vegetable gelatines. Foods rich in minerals are celery, apples, tomatoes, greens, oranges, and practically all the fresh fruits and vegetables, especially the small berries. Melons and starchy vegetables in large quantities are suitable for muscular workers. Use as little as possible of so-called pure chemical substances, such as refined sugar and flour.

Avoid poisonous beverages, tobacco and all forms of drugs. Sleep at least nine hours in a well ventilated room, facing east or south. Avoid constipation. Combine mental work with moderate amounts of useful and enjoyable exercise, or physical work. Protect the eyes from strong artificial light. Keep the feet warm. Relax before and after meals. A certain amount of manual labor is absolutely necessary for the brain-worker. It favors deep breathing and creates a demand for more air and water, and thus improves digestion, oxidation and nutrition. The body poisons are carried off quicker and nervous headaches and despondency are avoided. Short walks out of doors before retiring are very beneficial for people who suffer with cold hands and feet.

“THE IMMIGRANT.”

All who leave the land of their birth should make themselves acquainted with the art of living and the peculiarities of the new country in which they intend to live.

To depart entirely from their old customs and habits is as dangerous as to neglect the study of the new environment or the failure to adopt necessary changes.

In some States the climatic conditions of the United States are very changeable; we have extreme heat and cold, and excess of rain with wind storms and dryness changing within a short time. West of the Rocky Mountains we have a mild sea air. In the Southern States and near the Pacific Coast we have low districts where malaria and catarrhal conditions are easily acquired.

Tropical fruits and vegetables which are looked upon as luxuries in Northern Europe are necessary articles of food in the country where they grow, therefore the stranger should make himself acquainted with such foods and by degrees learn to eat them.

In countries where the days are extremely hot and the nights are cold, the selection of foods should be made accordingly. Fats produce more than twice the amount of energy than carbohydrates, therefore they are more suitable during the early part of the day. During the middle of the day select foods of the protein class, in proper proportion with fruits and raw greens. For the evening meal use the stimulating sub-acid and sweet fruits in combination with light protein and cereal foods.

HEALTH HINTS FOR BUSY PEOPLE.

1. Keep the feet warm, the head cool and the stomach not too full.

2. Take walks out of doors daily and breathe deeply.

3. Do not wear tight shoes or tight corsets.

4. Masticate your food thoroughly. Select, combine and prepare it rightly. Do not overeat.

5. Avoid fresh breads, inferior cakes and pastry.

6. Do not eat unless you are hungry.

7. Do not over-indulge in athletic or any other kind of exercise.

8. Remember that natural feeding, pure air and sufficient sleep call for natural breathing and natural exercise.

9. Unnatural feeding and late hours create disease or nervousness.

10. Don’t take drugs for sleeplessness.

11. Tired feeling in the morning is the result of nerve starvation and auto-intoxication.

12. The house we live in should be constructed for health and comfort, rather than for style.

13. Sleep by open windows. Night air is as pure as day air. Protect yourself from dampness by an open fire if necessary.

14. Do not dress and wash in a cold bath room. Have your wash bowl in the bed room.

15. Sewer gas from a small pipe in a well ventilated bed room is not harmful, as it is carried off in the air. Have the stopper placed in the hole when not in use.

16. Dress by an open fire or in a sunny room. A chill before breakfast produces indigestion and a desire for unnecessary hot foods.

17. Never sleep by night lamps or any other artificial light. They are injurious to the eyes and absorb oxygen.

18. Teach a growing child that selecting and preparing his food is an important occupation.

19. Do not allow a child to fill his body with trash.

20. Pure water is as important as pure food. If you boil your water the minerals are deposited on the bottom of the kettle instead of in the system for bone-making material.

21. Milk is a food, not a drink; it should never be taken in addition to, or at the end of, a heavy meal.

22. Many people object to boiled milk on account of a theory that it tends to constipate. Do not dwell on theories; find out the effect for yourself. Potatoes, toast and many other cooked foods are constipating also. Why not object to those?

23. Raw foods are more nutritious than cooked foods, if they are pure and fresh and can be digested without difficulty.

24. A change from cooked to raw foods might produce diarrhœa or constipation. The latter condition is generally not dangerous. Constipation from cooked foods is more dangerous.

25. A daily evacuation of the bowels is not always a sign that the stomach and intestines are in good working order. The bowels can be forced to move by the eating of too rich foods.

26. Some people are clearer in mind on a vegetarian diet, while upon others it has no such effect at all.

27. A healthy individual does not need to confine himself to a special system of diet. Avoid dangerous experiments carried on for orthodox reasons.

28. Rich soaky cooked nut foods are not health foods. If you want to be a vegetarian, live on raw foods.

29. Some people thrive on raw foods while others do not. The best time to begin with raw foods is in childhood.

30. Hot house plants cannot digest raw foods. Open your doors and windows and learn to breathe first. Fresh air and sunshine are necessary for the change of food.

31. If your teeth are poor, substitute a food-chopper or grinder for your foods.

32. The most perfect foods, such as apples, tomatoes, wheat, oats, rye, legumes and nuts seldom disagree with a healthy individual, provided they are used wisely.

33. Sunlight is a great disinfectant. Dark rooms are a breeding place for tuberculous germs.

34. Daily out-of-door exercise in the sunshine will increase health and reduce the coal bill. Without exercise our food can be of little benefit to us.

35. By natural feeding, overwork is not possible. The body demands rest when its strength is exhausted.

36. Artificial stimulants are deceivers. They make a man feel strong when he is weak. They produce artificial heat and will-power and an abnormal temperature; they lead to overwork, abnormal development and degenerate brains and bodies.

37. Natural will-power can direct its force wherever it is wanted, be it for work or rest; it can sustain on bread and water for many days.

38. Without substance there can be no power. Substantial food, fresh air, water and natural exercise develop strong bodies and minds.

39. Artificial sweets, white bread and poisonous beverages develop butterflies that crave excitement and artificial life.

40. The world is full of people that are without substance, power or principle. They earn their living the easiest way they can. Wrong feeding is responsible for such conditions.

41. Social reformers and humanitarians cannot solve problems until they have learned how to feed the race.

42. Many people are under the impression that if a certain food is recommended as especially healthful, over-indulgence must be beneficial.

43. All natural foods are wholesome; over-eating produces discomfort and disease.

44. Some fruits and vegetables have high medicinal values. Specific foods prescribed in large quantities are useful for certain ailments, but not for a healthy individual.

45. Each individual is a law unto himself. Two different people afflicted with a disease of the same name may require entirely different treatment. Human beings cannot be standardized like inert machines.

46. Canned fruits out of season are not a necessary article of food; they are of value as a medicine.

47. If certain foods do not agree, or produce indigestion, study their combination and preparation carefully, also the proportion, and time of the day when most suitable. If this does not prove satisfactory, leave them alone.

48. Don’t buy cheap or inferior food of any kind.

49. Don’t always believe your dealer as to the quality of the product. Investigate for yourself.

50. Don’t use fruits in excess if you lead a very active life. The right proportion is the key note to maintain balance.

51. Excessive fruits and rest is a prescription for sickness.

52. If no great hunger is felt at a meal, do not eat nuts or any kind of foods classed as protein. Neither stuff yourself with liquid foods. A fast or fruits or fruit juices are the best under such conditions.

53. Do not offer a guest more food than he desires. It may be polite, but it is an unwholesome fashion.

54. Drink sufficient pure natural water between your meals. There is danger in over-drinking as well as in under-drinking.

55. A definite employment, practical and loving sympathy with our fellow men and faith in the almighty power of creation is a good prescription for imaginary diseases.

56. There is a great medicinal force in a mind of peace. If you suffer from chronic ailments brought on by overwork, seek rest and solitude, and exercise your soul. The latent powers within you can be awakened by right study. Give up wrong thoughts and habits.

57. Hard arteries are the result of high-pressure life.

58. Restlessness and sleeplessness are the result of an acid or toxic condition of the blood.

59. The liver is the great filter and germ destroyer of the body. Co-operate with nature and treat your liver right. Germs are not attracted to healthy people.

60. Many lung diseases are often the result of an abused liver.

61. Mouth-breathing is the result of structural and functional derangement.

62. Children that are allowed to sit with cold feet in the school room cannot keep their health or study their lessons.

63. A destructive or mischievous child can be corrected by proper food and sufficient suitable employments.

64. Defective teeth and eyesight are often the result of improper feeding. Glasses cannot make up the deficiency.

65. Cleanse the mouth and teeth on arising and after each meal.

66. If you wish to prevent colds, stop overloading your stomach.

HYGIENE ECONOMY AND SANITATION.

The pantry shelf with its contents is responsible for many acute diseases and ptomaine poisoning by unhygienic and careless handling and preservation of foodstuffs.

A closet for the preservation of food should be located on the north or east side of the house if possible. It should have several long and narrow windows from top to bottom, so as to allow plenty of air and light. The shelves should be constructed of wire, zinc or wooden slats, and be removable.

Raw fruits and vegetables should never be kept in the same closet with cooked food. Milk and butter should not be kept near meat or other cooked foods. Potatoes, carrots and underground vegetables should be kept out of doors or in a dry basement. They may be preserved in a box with dry sand.

Onions should not be left in a paper bag; hang them up in the sun or keep them in a flat box in a dry place. Onions which have been cut should never be used again for food, unless the cut side has been preserved in vinegar or oil.

All raw foods which have a thick skin have better keeping qualities than those with a thin skin; therefore, fancy summer fruits should be eaten while fresh on the same day they were picked. No more should be bought than can be eaten the same day, or else they should be preserved by sterilization.

Green vegetables should be used fresh if possible, and not kept longer than three or four days. Never keep them in the house or pantry.

Apples or other winter fruits should be kept in a dry store room out of doors, in the attic or in a dry basement.

The white film that often gathers around grapes is a breeding place for diphtheria germs. Wash thoroughly before eating all fruits which have been stored in houses or at the market. Do not prepare more raw food than can be eaten at one meal. Never allow it to stand after it is cut.

Many housekeepers think it important to scald their dishes, but do not know that it is far more important to sterilize or reboil cooked foods which have stood on the shelf for 18 or 24 hours and sometimes longer. Such foodstuff is dangerous long before the process of fermentation can be detected by the sense of smell or taste.

Some foods begin to undergo changes immediately after cooling; therefore, cooked foods left over, with the exception of a few, should be reboiled before serving again. Rice or other cereals should be stirred over the fire for a while and then baked in the oven until they are thoroughly sterile. The care of milk has been discussed in the chapter on food. Soups which are preserved with fat will keep wholesome for several days without reboiling. Fruits and fruit juices should not stand longer than 24 hours. Eggs are best preserved in bran or lime-water or on ice if kept for a week or longer. Boiled or thoroughly roasted meats will keep wholesome for 36 hours in a cold place. During the summer meat should not be kept from one day to another.

If left-over meat is cut from the bone and cooked up in gravy or soup stock or preserved in gelatine (with fat to cover it), it can be kept wholesome for 4 or 5 days and longer, according to the manner of preservation. Half cooked chops and beefsteak should never be kept in the same manner they are served. They should be cooked thoroughly in fat or gravy before being put away. All meats should be freshly cut and cooked the same day after delivery, or be preserved by partly cooking or roasting, until the next day. Many housekeepers keep roasts, chops and beefsteak until it looks blue and green with putrefaction before it is cooked. Never buy meat which has an unnatural color. Be sure that your butcher does not use poisonous substances to keep the meat from decomposition. Visit your butcher often and investigate how often he gets a fresh supply of meat. This is of more benefit than to save time by telephoning.

Never allow sliced bacon to lie in the ice box or pantry for several days. It becomes rancid and is unfit for food. Buy your bacon in bulk and slice it with a sharp knife when wanted.

Do not keep sliced meat of any kind longer than one day in cold weather. Do not keep it in hot weather without preserving it in gravy or fat or by sterilization.

Do not keep a tight cover on a dish, jar or bottle which contains raw or cooked food, unless the air within is sterile.

Allow cooked food to stand open until it is cool, then put the cover over two-thirds of its opening or cover with a cheese-cloth or a colander.

If milk or cream is delivered in bottles, remove the cover immediately after delivery. If the air where it stands is dusty, protect the milk with cotton or cheese-cloth. Treat boiled milk in the same manner.

Cooked foods which have poor keeping qualities should not be kept for further use, or no more should be prepared than can be eaten at one meal. To this class belong cooked underground or leaf vegetables, custards, soft puddings, milk and egg foods and gelatines. Damp or rainy weather is more favorable for decomposition of foodstuffs than dry weather.

Whites of eggs should not be kept longer than 18 or 24 hours. They must be preserved in a very cold place and be utilized at the earliest opportunity. They are like all proteins, more dangerous than starches if left to ferment, whether the fermentation begins on the pantry shelf or in the stomach. White of egg can be used in many different ways. It may be beaten to a froth and served on fruit-soups or fruit pies, or it can be taken in place of broth at the beginning of a meal. Add a tablespoon of water and a few drops of lemon or orange or apple or cranberry juice to one white of an egg and beat up with a fork, or drink without beating. White of egg can also be utilized for brancakes.

If a variety of left-over food is on hand which cannot be combined into one dish, it is better to serve different food to each member rather than to divide each article for all; the latter custom may be more polite, but it is not wise to mix a great variety of foods at one meal.

Left-over skim-milk is best utilized for cheese, pancakes, whey gruel, whey or milk sauce, or be boiled and served with stale rye or corn bread. Vegetables prepared with milk do not make a good combination. Soft puddings prepared with skim-milk, sugar and eggs, are not very wholesome unless the necessary amount of fat is added in the form of butter or suet. Skim-milk and fruit is not a good combination.

Left-over potatoes can be utilized in many different ways: for fish-cakes, pancakes, hash, potato-dumplings, creamed potatoes or for salad. Fried cooked potatoes are not a good food for the noon meal, especially for children or people doing active work.

Baked legumes if preserved with fat meat or oil can be kept on hand for a week and be rebaked two or three times per week.

PRESERVATION OF EGGS FOR THE WINTER.

Put one layer of common salt or bran one inch deep on the bottom of a wooden pail or washtub. Then grease the eggs with parafine or oil and place them with the small end down, so that they will not touch the bottom of the tub. Fill with enough salt to cover the eggs one inch.

PRESERVATION OF EGGS. No. 2.

Preserve the eggs with salicylic acid, which can be bought in the drug store. Follow directions on package.

CHILDREN.

A child should have his face and hands washed before and after each meal. He should not be allowed to carry foodstuffs and candy about the house, or touch carpets and furniture with sticky and greasy fingers. If he requires food between meals, give him four or five meals per day, but have him eat his food in the proper place.

The breeding of flies, mosquitoes and other disease carriers is greatly favored by allowing children to eat at any and all times without napkins or special preservation of their dress or without cleaning their hands before and after eating or before and after playing with animals and pets.

The American child is given too much consideration at the table. There is a great difference between the saying “I don’t like a certain food” and “I don’t want it,” because there are things which taste better.

To leave one’s plate half full of foodstuffs and ask for or accept another food is fashionable, but before the law of our Creator it is unclean and disrespectful.

The physiological laws of our bodies are based on very economical plans; nature utilizes everything and wastes nothing. Cooked foodstuffs, whether they are wasted within our bodies by over-indulgence, or in the garbage can, create decomposition and germs.

Cooked green foods and mushes are neither wholesome foods for chickens or pet animals. Natural food is dry, and animals which are fed on dry food produce a better quality of milk, eggs and flesh than animals which are fed upon slops.

DISHWASHING.

Dishwashing is a work which takes up so much time in every household, that it is a subject which should receive some attention.

The housekeeper who serves a considerable amount of raw food saves much time and strength by relieving herself of greasy dishes and saucepans.

Scrape off the fragments from plates and utensils and prepare one basin with hot soapsuds and another with rinsing water of clear hot or cold water. People whose time is valuable can save much work by placing the dishes from the drain-board upside down on a shelf prepared from wooden slats, or set them in a wire basket and let them dry without wiping.

If the dishes are not washed immediately after each meal, place the silverware and knives in a high bowl or quart measure and let them soak in hot or cold water. Remove all foods from metallic utensils immediately after the meal is over. Never allow metallic spoons to stand in fruit sauce, salt or in any kind of prepared food. Acids dissolve metal and in this way may produce poisoning.

In contagious diseases all dishes should be sterilized. Burn up all particles of left-over food, put the dishes into a narrow pail and boil with plenty of water and soda for an hour or longer.

DISINFECTION OF EXCRETA.

Use solutions of carbolic acid or chloride of lime. Mix with equal quantities of the excreta and allow it to stand for several hours before it is disposed of.

WHITEWASH FOR WOODWORK.

Soak one-fourth of a pound of glue in cold water over night. Dissolve some lime with cold water, add a few handsful of salt. Heat the glue until it is dissolved and add to one bucket of whitewash. This makes a smooth and healthy paint. Use for rough or smooth woodwork, twice per year in laundry, basement or cellar or pantry.

[1] Refuse, oil.

[2] Refuse, shell.

[3] Plain confectionery not containing nuts, fruit, or chocolate.

[4] Such vegetables as potatoes, squash, beets, etc., have a certain amount of inedible material, skin, seeds, etc. The amount varies with the method of preparing the vegetables, and cannot be accurately estimated. The figures given for refuse of vegetables, fruits, etc., are assumed to represent approximately the amount of refuse in these foods as ordinarily prepared.

[5] Fruits contain a certain proportion of inedible materials, as skins, seeds, etc., which are properly classed as refuse. In some fruits, as oranges and prunes, the amount rejected in eating is practically the same as refuse. In others, as apples and pears, more or less of the edible material is ordinarily rejected with the skin and seeds and other inedible portions. The edible material which is thus thrown away, and should properly be classed with the waste, is here classed with the refuse. The figures for refuse here given represent, as nearly as can be ascertained, the quantities ordinarily rejected.

[6] Milk and shell.

[7] The average of five analyses of cereal coffee grain is: Water 6.2, protein 13.3, fat 3.4, carbohydrates 72.6, and ash 4.5 per cent. Only a portion of the nutrients, however, enter into the infusion. The average in the table represents the available nutrients in the

beverage. Infusions of genuine coffee and of tea like the above contain practically no nutrients.

TABLE II.--_Food consumption of persons in different circumstances, and proposed dietary standards._

Causes of Constipation 7

Exercises for the Prevention and Correction of Constipation 20

CONSTIPATION AND ITS CORRECTION BY EXERCISE

Constipation or dyskinesia is one of the important influences in making people old before their time. The breaking down of the faculties and functions supposed to be due to old age is in reality due to the accumulation of waste and bacteria in the intestines. A habit of life which keeps the bowels clean will set "old age" back to the time when men will enjoy perfect health to the utmost limit of a normal span of years (at the present time the normal span is fifty-eight years).

There are many people who think they are quite normal, though they never had a regular daily movement of the bowels without the aid of laxatives in years. Yet, these same persons will not let the gasoline line on their automobile stay clogged one day.

The body is a very delicate organism and it must be taken care of in a thoughtful fashion. A poisoned night is spent if a day is missed without a bowel movement, for the body cannot carry waste a great length of time without serious injury to it. Under a normal life the bowels should move at least once a day without artificial aid.

Results of Constipation

When food remains too long in the body it decays, putrefies, and develops into very active poisons. With this decaying comes a depressing feeling caused by these wastes being absorbed into the blood. Then, to make matters worse, this putrification retards the bowel action, thus keeping the poisons in the body. Thus, constipation results. Some of these poisons are not so harmful, yet others are very capable of infecting the body, and these enter the blood stream via the intestines and reach other organs where they may cause a chronic disease.

Constipation brings many other ills besides that of poisoning and infecting the body. If this decay occurs too frequently, very serious infections may develop. Frequently diseases associated with old age, such as rheumatism, kidney trouble, and disturbances of the gall bladder are the result of a constipated condition which has run for years. The retained masses of putrefied food in the digestive tract many times displaces and distends the bowels with the ultimate result that it reacts on the nervous system and the circulation of the liver, and causes much suffering. Appendicitis is often traced to the continuous constipated condition.

Other results of constipation can be dizziness, offensive breath, headache, loss of pep and vitality, bad temper, poor complexion, stomach disorders, skin eruptions, sleepless nights, loss of appetite, stupor, and piles.

CAUSES OF CONSTIPATION

Lack of Exercise

One who leads an inactive life must expect to have a flabby body. Lack of exercise lowers the tone of the whole body and especially the abdominal viscera. This is an unhealthy way to live, for it offers no incentive to the stomach and intestines for the vigorous digestion of food. A good workout daily will stimulate and tone the intestines for better functioning.

Unless your work involves a great deal of outdoor walking, a daily walk cannot be over-estimated in the treatment of constipation. Learn to stride along with the head and chest up, breathing deeply. Walking in this fashion will do as much good the last ten minutes as the first ten. This exercise will stimulate the appetite and increase the physical and mental tone of the body. It is a life-enriching as well as life-purifying habit.

Learn to take a few workouts in the gym every week, that is, if you are physically able. However, before you plan your workout have your health doctor plan your program and limitations and what it should include.

In the back of the book will be found exercises that will aid in the correction of constipation. These exercises will be found very beneficial if used daily.

Improper Diet

One of the chief causes of constipation is improper diet. Correct feeding alone may cure constipation. Even this rule has its exception, for there is a form of constipation associated with proper diet. This brings out the point that it is essential to have a health examination frequently by your family doctor, for he will give you correct knowledge of the condition of your body immediately.

Before taking up the matter of food, it must be remembered that the purpose of this book is to give exercises to cure constipation and not to plan a diet. Your doctor will give you a correct diet. However, it is essential that the food should be chewed until it is almost a pulp before swallowing. This will aid the stomach and whole digestive tract in assimilating the food.

The spirit of happiness and cheerfulness is important when eating. It cannot be over-emphasized. In fact, laughter during the meal time is very good for the digestive tract in digesting the food. This buoyancy of the mind will aid a great deal in the correction of constipation. It is the only exercise that can be used successfully while eating. Do not be downcast while eating, as this will prevent normal digestion.

The typical breakfast is usually orange juice, eggs, toast or rolls and coffee. This breakfast will satisfy hunger and supply energy, but it does not meet the demands of health. It is true that this breakfast includes the necessary nutriments, but it does not contain bulk or roughage, which are sometimes desirable in order to give the bowels something to work upon.

In order to give the body foods with roughage bran may be used in moderation. However, bran does not agree with everyone. The indulgence in this food should depend upon the advice of your physician.

Fruit will cure constipation quicker than any constipation remedies ever advertised. Oranges, orange juice, figs, dates, and prunes are very good for the prevention as well as the correction of constipation. It is a very excellent idea to have some form of fruit for every meal. It cannot be over-emphasized.

Vegetables are an absolute necessity in everyone’s diet. Nature gives us food values that cannot be estimated in importance. They clean the interior of the body and act as a broom in the digestive tract, that is, if they are eaten twice a day. They are a mechanical necessity to the intestines. Their bulk is absolutely needed to stimulate the intestines to activity.

Foods which contain no mechanical stimulation such as purées and gruel are open to objection. Pastries are very constipating due to the pasty element, for the secretions of the digestive tract cannot assimilate them. The psychic effect of a monotonous diet may cause poor digestion resulting in constipation. Such foods as eggs, milk, cheese--particularly cottage, pot smearcase and cream, white rice, tea, chocolate are said to be constipating because they seem to slow up the action of the intestinal tract.

On the whole, eat foods that originally gave the human race its vigor, and you will get all the food values, the sunshine, and fresh air, which that food has absorbed during the days of its growth.

Laxatives

Laxatives do not cure constipation. They may serve to make it chronic. Yet one fourth of the people use them regularly. They only give artificial stimulation to the bowel movements. Every laxative, no matter how innocent in itself, is a habit forming drug for the bowels. They lash the bowel into action once or twice or a few times. After that the bowels will refuse to work without a laxative administered. The dose becomes larger and larger until heroic doses are consumed. NO LAXATIVE OR ANY FORM OF BOWEL WASHING SHOULD BE TAKEN UNLESS ADVISED BY A PHYSICIAN.

Posture

Poor posture ranks on a par with lack of exercise and improper diet in the cause of constipation. Poor posture aids in the slipping of the abdominal organs out of their respective places, resulting in a tangled mass which will act as an interference on the normal bowel action. As a general rule, poor posture hinders deep breathing. Thus, there is no compressing movement upon the organs of the abdominal regions, such as is found in a normal upright person. Deep, vigorous breathing is an aid to a normal bowel movement. Good posture is an absolute necessity for the freedom of the bowel acting.

During Defecation

Faulty posture during defecation causes insufficient emptying or difficulty in moving the bowels at all. Many closet seats are too high. The proper altitude is one that brings the knees a little higher than the posterior.

A high closet seat can be remedied by using a footstool to support the feet, thus bringing the body into proper posture.

Hurried Defecation

A normal defecation ordinarily takes about two to three minutes, but owing to the abuse of resisting the call, ordinary defecation is not always secured in the normal time. Thus residue is left in the large intestine. This offers difficulty when a call comes some later hour, for the residue becomes hard and dry. This residue in the colon results in the condition known as

Irregularity in Answering Call

Irregularity in answering nature’s call causes irregularity of bowel action. Nature’s call means that enough waste is in the colon to cause automatic processes to set in action the bowel movement.

If for any reason the bowels are not permitted to move at once, the call usually disappears in a few minutes and may not reappear for some time. Thus, the wastes lie in the colon with the water in them being absorbed by the intestine, causing the wastes to become dry. Due to these wastes remaining in the intestine distention is produced in the colon and defecation may become difficult or impossible without mechanical aid.

The water of the waste which is absorbed into the blood stream affects the body, causing lower vitality and fatigue affecting the nerves.

Treatment

Hygiene is an important factor in restoring the body to a condition of health. The various abuses of the body that make for constipation should be corrected. General habits, and especially that of neglecting nature’s call, should be corrected. Without good hygiene the treatment of constipation cannot be successful.

Proper Diet

See your doctor and have him make out a proper diet. However, the diet should contain a sufficient amount of roughage, such as vegetables, fruits, and bran. Milk should be used for its vitamin qualities and nourishment.

Rules for Proper Eating

1. Do not eat too much.

2. Do not study your food while eating.

3. Enjoy what you eat.

4. Chew your food until it swallows itself.

5. Eat regularly.

6. Do not eat when tired.

7. Take a brisk short walk after eating, as this is an aid to the digestive processes.

Laxatives and Enemas

These should be used only upon the consent of your doctor. They do not cure, and if possible should be avoided.

Mental Attitude

Patience is necessary, and the feeling “I can’t” should be changed to “I will.” This feeling can do more than drugs. Do not hurry defecation.

Regularity

Visit the toilet at least once a day--not to read but to move the bowels. Aim to establish a habit by visiting the toilet the same time every day.

Use of Water

Most people drink too little water. Six glasses of water a day is the minimum and eight are better. Even more should be taken in hot weather. Avoid ice water, for it chills the stomach. If ice water is the only water available, sip it slowly.

Water should be taken freely between meals. A glass at each meal will help digestion, and there is nothing that so helps the bowels as a glass or two of water before retiring.

Bathing

After taking the exercises described in the back of the book a bath should be taken. Take a shower or tub bath for two minutes with the temperature between 95° and 100° F. for cleansing purposes. This should be followed by a quick cold rub over the entire body. Dry with a rough towel until the skin glows. This should be followed by a cold wet towel rubbed on the abdomen for a few minutes until it attains a reddish glow. Then dry the body thoroughly, dress quickly, and you will have a keen appetite for the morning meal.

Exercises

The effectiveness of certain exercises in overcoming constipation has been scientifically proved. Diet alone will not cure constipation. Diet and exercise should be used together, and the victim of constipation should not neglect either. Suitable diet and proper exercises can usually be relied upon to cure the most obstinate case of constipation. They will very frequently banish that tired feeling and make one tingle with energy and vitality.

Every one needs exercise other than his work, for work tires the same old muscles and the same old back day after day, while it neglects the vital muscles around the waist. Work wearies, while exercise refreshes. Exercise builds up the muscular system and makes work easier. Exercise may be harmful if too vigorous, and if the patient is not accustomed to it. These exercises as described below should be indulged in mildly at first, and as the body becomes accustomed to exercise increase the dosage.

Monotony in doing the same old exercise cannot be condemned too vigorously. It is better to spread the dosage of work around the different parts of the body rather than to concentrate too vigorously on the muscles of the waist. The continuous repetition of certain movements results in fatigue, which causes atonic conditions about the parts involved.

Regular exercises in the open air and getting the abdominal muscles and organs in first rate condition is the first step in securing longevity of life and renewed vitality. This will increase the appetite and strengthen the voluntary muscles of defecation. Vigorous exercise diverts the thoughts from business and household cares and relieves an important factor in constipation. Hill climbing, walking, running, horseback riding, and all forms of games are the best forms of exercise for the cure of constipation. It so happens in many cases that the individual is not physically fit for such activities, and then the following exercises cannot be used to advantage until the patient is able to participate in recreative exercises and games.

In the following exercises that of raising both legs to a right angle from the lying position is purposely omitted because of the severe action on the abdomen and the paralyzing effect on the sensitive nervous systems of that region. Often an exaggerated condition of constipation comes from this type of exercise.

In the following exercises it must be remembered that good posture is necessary for the proper effect on the vital organs.

EXERCISES FOR THE PREVENTION AND CORRECTION OF CONSTIPATION

EXERCISE 1

Position: Lying on back on floor, hands on sides, legs straight.

Action: Arch the body upward, forming a bridge with the weight resting on the heels and shoulders.

Remarks: This is an excellent exercise before retiring. It can be done ten to twenty times without fatigue.

EXERCISE 2

Position: Feet apart, arms side shoulder level.

Action: Twist the body to the right side, bend slightly forward, keeping the knees straight and touch the right foot with the left hand, the right arm being stretched straight up over the body toward the ceiling. Exhale and draw abdomen well in. Repeat exercise twisting the body to the left side and touching left foot with right hand.

EXERCISE 3

Position: Lying on back on floor, hands by sides, legs straight with the weight of from two to four pounds on the abdomen.

Action: Breathe slowly and deeply. The abdomen should rise and fall rhythmically as you breathe.

EXERCISE 4

Position: Body erect and on toes.

Action: Full knee bend, extend arms forward. Exhale and draw abdomen in. Rise to normal position, keeping abdomen in. Raise the chest and then inhale.

EXERCISE 5

Position: Feet apart, arms side shoulder level. Twist the body to the right side, lean slightly over the right knee; inhale. Return to normal position, then repeat to the left side.

Remarks: All twisting is done above the hips.

EXERCISE 6

Position: Stand erect with chest up, chin in.

Action: Bend or sway from side to side, moving from the hips only.

Remarks: The arms should wave loosely like the branches of a tree.

EXERCISE 7

Position: Lying on back on floor, hands by sides, legs straight.

Action: Draw the right knee to the chest and exhale. As the right knee is returned to its normal position the left knee is drawn to the chest.

Remarks: A variation of this exercise for those whose abdominal muscles are weak, the knee may be lifted to the chest and compressed to it by both arms being wrapped around it.

EXERCISE 8

Position: Lying on back with the body well relaxed.

Action: Expand the chest, pulling it well up and letting the abdomen become hollow. Count six. Then make the chest small, pushing down and making the abdomen large and count two.

Remarks: Do this three to five times without breathing; then take several slow, long breaths. Repeat this exercise from fifteen to twenty times. A variation of this exercise may be done by getting down on all fours like a cat, and doing this exercise.

EXERCISE 9

Position: Stand erect with hands resting on hips.

Action: Raise the right knee until it is at right angles with the body, with the toes pointing towards the floor. Extend the foot forward until knee is straight and stretch. Return leg to normal position and repeat with the left leg.

EXERCISE 10

Position: Stand erect with hands resting on hips.

Action: Stationary run, with high knee action, that is, bring your knees up well in front of you and land on the balls of the feet.

EXERCISE 11

Position: Same as Exercise 10.

Action: Draw the right knee to the chest and squeeze with both arms. Raise on toe of the left foot. Replace the right leg and continue exercise by repeating with the left leg.

Remarks: An alternate compression and stretching movement is given the abdominal organs.

EXERCISE 12

Position: Stand erect with fingers interlaced behind the neck.

Action: Draw the abdomen in; lift the chest and look straight up towards the ceiling directly above you. Turn your head slowly to the right and then to the left.

Remarks: Do this exercise about six times. This is a very good exercise before taking the morning shower or bath.

EXERCISE 13

Position: Stand erect with the hands above the head.

Action: Bend body forward and touch toes with the hands. Exhale and draw in the abdomen. Return to the normal position and inhale.

EXERCISE 14

Position: Lying on back with the hands tightly closed on the shoulders.

Action: Lift the chest and take a deep breath. Put your head back; then bend the body to the right. Stretch the left arm forward and the right sideward. Stretch vigorously. Exhale and return to the normal position. Repeat to the left side.

Remarks: This is an excellent first exercise in the morning workout. It can be done while lying in bed. Yawn, stretch, and grunt as much as you wish for the circulation is stimulated.

EXERCISE 15

Position: Sitting on chair directly below the chandelier or light fixture.

Action: Keeping head directly underneath chandelier, make a circle with the abdomen from right to left, or from left to right. Crumple down, then straighten up and you are making your circle.

Remarks: Do this ten to twenty times. It is one of the best exercises for the cure and prevention of constipation. It may take some time before one can make the circle in a real circular fashion.

EXERCISE 16

Position: Feet together, standing with the hands above the head.

Action: Twist the body to the left side. Place the left hand on the hip, and with the body in that twisted position, touch the outside of the left heel with the right hand and exhale. Return to normal position and repeat to the right side.

Remarks: Knees should be straight during the entire exercise. It may be impossible to touch the heel, but stretch down as far as possible. In returning to the normal erect position, bring the hand out and up.

EXERCISE 17

Position: Lie on the back in form of a cross with arms extended.

Action: Carry right foot up to the left until it touches the left hand. Repeat, using left foot touching right hand.

Remarks: A difficult variation of this exercise may be done by doing the exercise in a standing position.

EXERCISE 18

Position: Lying on back with arms above head on floor keeping knees straight.

Action: Assume a sitting position and touch toes with hands; exhale. Return to sitting position, keeping abdomen in; then slowly return to the normal position. Stretch and then inhale deeply.

EXERCISE 19

Position: Body erect, hands on hips, feet apart with knees straight.

Action: Bend to right, then to left.

Remarks: Do not bend too far backwards. Repeat this exercise about a dozen times.

EXERCISE 20

Position: Body erect, chest up, feet apart.

Action: Turn head and shoulders to right as far as possible. Then swing arms, head and shoulders in the opposite direction.

Remarks: Waist muscles should be as lax and lifeless as possible. Let them twine around the body as if tied to the body with strings. This should be a daily exercise and can be used by people of all ages. It is very beneficial.

EXERCISE 21

Position: Stand erect with hands on hips.

Action: Bend right and reach towards floor or ground. Reverse movement to left.

Remarks: In reaching towards floor bring the hand only to the knee at first and then with each successive stretch bend a little lower until ground is reached. This exercise is very helpful in preventing or curing constipation and torpid liver.

EXERCISE 22

Position: Stand erect, hands on hips, feet apart.

Action: Swing hips as far to right as possible then to left. Keep head as nearly as possible in starting position.

Remarks: Hold hips a second or two in each position: _i. e._, right or left.

EXERCISE 23

Position: Body erect, hands on hips.

Action: Bend forward very slowly, hinging only at hips, while keeping back straight and face to front. Bend low enough so that back is parallel to floor. Return to normal position slowly.

Remarks: You will not like this exercise at first, but it is a very helpful exercise. Repeat exercise three to five times.

EXERCISE 24

Position: Stand erect with hands high above the head.

Action: Bend to right and bring hands to floor near the right foot, going down slowly. Reverse movement and swing hands directly over head and down to floor near left foot.

Remarks: Repeat in each direction four or five times. Combine deep breathing with this exercise; exhale as you bend in one direction and inhale as you reverse movement.

EXERCISE 25

Position: Stand erect with hands on hips, feet together.

Action: Bend forward until back and legs are at right angles. Turn right by pivoting at waist and swing head and shoulders around in a large circle until they have been returned to starting position. Reverse movement and swing around in opposite direction.

Remarks: Keep knees straight. Do not bend too far backwards. This is a very strenuous but very effective waist strengthener and liver stimulating exercise. (Do not use until you are accustomed to exercising.)

EXERCISE 26

Position: Stand erect.

Action: Take a full breath, hold it, reach out right and left, close fists tightly and tense arms. Repeat two or three times. Now take another deep breath and reach as far as you can with the feet while tensing the muscles of the legs.

Remarks: This is an excellent exercise in beginning the morning workout.

EXERCISE 27

Position: Lying on back very lax and lifeless.

Action: Take a full, deep breath very smoothly through the nostrils and at the same time expand the abdominal muscles as much as possible. Hold breath a few seconds, relax waist and abdominal muscles very slowly and then draw in and upward and exhale. Repeat five to ten times or oftener.

Remarks: One of the best exercises a frail, weak person can take and quite as valuable for strong folk.

EXERCISE 28

Position: Stand erect, arms on level with shoulders.

Action: Swing right foot around to a position two feet from left side of left foot thus twisting the legs. At the same time swing head and shoulders as far around to right as possible while keep the arms straight and in line with each other. Reverse and swing as far as possible to the left.

Remarks: Repeat exercise eight to sixteen times. This is a good exercise to strengthen and make flexible a good many muscles of the body.

EXERCISE 29

Position: Stand erect, hands on hips.

Action: Right foot raised backward, bend forward until back and legs are at right angles, exhale. Return to normal position. Repeat exercise four times to both sides.

EXERCISE 30

Position: Stand erect with chest up, chin in.

Action: Expand chest and abdominal muscles suddenly while bringing hands up quickly above head at the same time taking a deep breath just as quickly as possible through the nostrils. Hold breath a few seconds then exhale very slowly as you lower hands to starting points. Repeat three to five times. Now take breath very slowly while bringing arms up laterally till hands meet above head. Bring arms back to sides very quickly and suddenly exhale completely through mouth. Repeat three to five times.

Remarks: Another part can be added to the above exercise by taking a deep breath and counting fifty without taking more breath.

The above exercises should be indulged in as you arise in the morning. They will give you pep and vitality that is needed to carry on a successful day. They will give the abdominal organs the workout that will prevent and correct constipation.

These exercises are in reality liver regulators. You will undoubtedly discover after doing these exercises that you feel better in every way.

It is essential to take several deep, long breaths between each exercise. Do not do the same exercises every morning. Pick out five and do them vigorously for fifteen minutes. There are enough exercises for six days of the week; thus you will not become tired of the monotony of exercises.

TRANSCRIBER'S NOTE

Obvious typographical errors and punctuation errors have been corrected after careful comparison with other occurrences within the text and consultation of external sources.

Some hyphens in words have been silently removed, some added, when a predominant preference was found in the original book.

All misspellings in the text, and inconsistent or archaic usage, have been retained.

London CHATTO AND WINDUS, PICCADILLY 1885 [_All rights reserved_]

PREFACE.

During the past few years, the introduction of a dry-plate photographic process of such a nature that it can be practised successfully by amateurs of both sexes has aroused an amount of interest in the camera and its capabilities, such as few scientific instruments can command. The Magic Lantern is now closely allied with the camera, for there is no means of showing the perfection of a photographic picture so well as by its aid. But many persons are deterred from adopting the latter contrivance because they fancy that there must be innumerable difficulties to surmount before they can hope to master its management. It is for these that the following pages have been written, in which I have tried to place clearly before the reader what can be done, and how to do it. I have also tried to indicate the educational value of the lantern, and have pointed out in a necessarily brief manner how various branches of knowledge can be illustrated by its aid. The numerous personal inquiries addressed to me after my lectures, and the numbers of letters constantly received, asking for information regarding the lantern, its management, and the preparation of lantern slides, have convinced me that there is room for a manual, humble though it be, dealing with these subjects.

CONCLUDING REMARKS.

The management of the lantern in public.--Signals between lecturer and operator 70-75

THE MAGIC LANTERN

AND ITS MANAGEMENT.

There is no optical instrument so well known or so highly held in popular estimation as the Magic Lantern. It is somewhat unfortunate that its old appellation, given to it when it was nothing more than a mere toy, should have stuck to it so long. And more than one attempt has been made by those conversant with its capabilities as a scientific instrument, and as an important aid to education, to give it a name more consistent with its real value. The late Mr. Dalmeyer was, I believe, the first to re-christen it the ‘Optical Lantern;’ and there is evidence that others are adopting the term, and that in time the old name will sink into oblivion.

With regard to the early history of this deservedly favourite contrivance, but little is known. Its invention has been ascribed to Friar Bacon, but the evidence on this point is of the most legendary character. It seems, however, certain that the first to give an intelligent description of it was Kircher--a Jesuit who lived two and a half centuries ago, and who published a work entitled ‘Ars Magna Lucis et Umbræ,’ or ‘The Great Art of Light and Shadow.’ The body of the lantern, as described by Kircher, consisted of a room several feet across, furnished with an opening in which a lens was placed. The source of light was an oil-lamp, and the pictures for exhibition were of the roughest kind. Indeed, we may presume that the effects produced fell far short of those attained by the cheapest toy lantern of our schoolboy days. Even if we search the columns of an Encyclopædia or any similar book of reference of forty years ago, we shall not find any great improvement on the description afforded by Kircher. The magic lantern will there be found described as ‘an optical toy, by which glass pictures executed with coloured varnishes can be thrown upon a wall or screen.’

But from this time a gradual improvement began. First, the old oil-lamp was replaced by the argand burner; then came gas; finally the brilliant lime-light--and some time in the near future, perhaps, will come electricity. The improved means of obtaining light have naturally led to larger pictures being thrown on the screen; for the size of such pictures is governed only by the amount of light available. Thus, supposing we own a modern lantern constructed with one of the improved three or four-wick lamps, and that it will give us a good picture of about six feet diameter, by using the same lantern, and without any change whatever in its optical arrangements, save fitting it with a lime-light jet, the disc can be increased to fifteen feet diameter. A picture of the same size could be produced with the original lamp, provided that the operator retired to the necessary distance from the screen, but the light would be so attenuated that the picture would be but a ghost of what it ought to be. It will therefore be understood that the enlarged image formed by the lantern lens can be made to fall at any point in front of that lens, and may be of any size; but to render it practically available its size, and therefore its distance from the lens, must be regulated by the amount of light at disposal.

During the past few years two circumstances have combined to render the optical lantern more popular than ever: one being the introduction of photographic transparencies representing scenes from the remotest parts of the earth, and the other the construction of metal-bodied lanterns of improved character, and burning mineral oil. As a good paraffine lamp is compared with a farthing rushlight, so is one of these lanterns to the toy of our boyhood. The light given, although it falls far short of the brilliance of the lime-light, is much more intense than could have been hoped for some years ago from oil. But its brilliance is not all due to the paraffine, but quite as much to the careful ventilation and general construction of the flame-chamber. There is, too, no danger in the use of this form of lantern, for the reservoir containing the paraffine is far below the combustion-chamber, and therefore it cannot become unduly heated.

The lenses, too, in this new form of lantern, although placed in the same position as those in the old-fashioned magic lantern, are of a very different stamp. And this leads me to a brief consideration of the optical system comprised in these instruments.

[Illustration: FIG. 1.

L, Light; _c_, _c_, Condensing lenses; _o_, _o_, Objective lenses.]

There are two sets of lenses: one being known as the condenser, and the other as the objective. The condenser is made up of two or more glasses, the usual form consisting of two plano-convex lenses placed face to face. The duty of this condenser is to take up as much as possible of the light afforded by the lamp, and to change the direction of the rays so that they are cast through the picture or slide placed in front of it. A glance at Fig. 1. will show how this is accomplished, and how the rays indicated by the dotted lines would be lost if not turned to account by the condenser. The use of the objective, on the other hand, is to magnify the image of the picture, and to present it in as perfect a form as possible on the screen placed for its reception. Its distance from the picture is governed by the distance of the lantern from the screen, and can be regulated to a nicety by the focusing screw attached to it. It is generally acknowledged by all acquainted with the requirements of the lantern that the photographic camera lens (known as the quarter-plate portrait lens) fulfils admirably this duty; and this particular form of lens, which is by no means expensive, is generally fitted to modern lanterns of the mineral-oil type. The condensers vary from four to three inches in diameter; perhaps the best size is three and a half inches. The relative positions of condenser, light, slide, and objective are indicated in the diagram to which attention has just been called, Fig. 1.

The optical lantern always inverts the image of any picture projected by it, an inconvenience readily obviated by placing the slide on the stage upside down. At the same time the picture must have its front turned towards the condenser, not away from it, otherwise every part of the slide suffers reversal on the screen. In some cases this does not matter, but when any wording, such as that on a signboard, for instance, is contained in the picture, it reads backwards. Such accidents can be prevented by a white label, easily seen in semi-darkness, placed in a certain position on the picture. If such a precaution had been observed at a certain exhibition at which I was present, General Garfield would not have been shown standing on his head--not a dignified position for the President of the American Republic.

The first lanterns, constructed to burn mineral oils, were very different to those of modern make, and took their pattern from the cumbrous instruments which before them were provided with colza-oil lamps. The reservoir for the oil was carefully kept in a cistern at the back of the lantern, and bubbled through a pipe to the lamp on the same principle that water is supplied to an earthenware poultry fountain. It was doubtless thought necessary in those days to maintain the paraffine in the cistern at a height equal to or above the wick, as in the case of colza and other heavy oils. But paraffine is more of the nature of a spirit--for it volatilizes very readily--and in modern lamps for lanterns the reservoir is kept some inches below the point of combustion. By the time that the

liquid reaches this point, it has become so heated in the course of its passage along the metal wick-holders that it issues as a gas. This can be readily proved by turning down the wicks after the lantern has been burning some time, when the flames will remain above the wick-holders, although the wicks themselves have been turned down quite out of reach. In the older lanterns, too, the glass chimney was thought to be indispensable, but now this has been done away with, and with it the cylindrical wick has also gone. The modern combustion-chamber is made of charcoal iron, and is closed at one end with a thin pane of glass, just outside which the condensing lenses are placed, and at the other end by a silver-plated reflector. The necessary air to promote combustion is admitted by suitable orifices below, and a draught is established by a long iron chimney above.

There is no great difficulty in managing one of these lanterns. The loosely plaited cotton wicks should in the first instance be carefully cut parallel with the wick-holders. After this they do not require much attention. It is a far better plan to remove the charred end of the wicks by scraping them along with the back of a knife, than to be always cutting them afresh. However, any loose strands that may project from the cotton should be certainly snipped off with scissors.

After lighting the lantern--which is best done with a long wax taper--each wick should be turned down quite low, and the combustion-chamber closed. In about two minutes, by which time the front glass and the lantern generally will have become warmed, the wicks should be turned up to their highest; that is to say, to a pitch just short of smoking-point. If the wicks are turned low for any length of time the lamp will be sure to smell. It will also smell if, in the process of charging with oil, some of the liquid has been smeared against any part of the lantern which may afterwards become heated. The best oil only should be used.

I have already hinted at the educational value of the optical lantern, but those who have not experimented with it have but a faint idea of its capabilities in this respect. I am of the opinion that every school and college should possess one, and that both pupils and teachers would soon discover its many advantages. Now that it is manufactured in such a portable and efficient form, and can be so easily managed, there is no possible hindrance to its adoption, unless it be its old name of ‘magic lantern,’ which is associated with things too childish for consideration. But this objection cannot hold good when it is pointed out how many different branches of knowledge can be illustrated by its use.

The schoolmaster of a London Board School once told me of some of his difficulties in teaching such a subject as geography. Most of the children had never seen the sea, and many of them had never even travelled so far as the Thames. What notion could such waifs have of a mountain, a valley, a cliff, or even of a rock? The value of the optical lantern at once becomes apparent here. But better informed children in high-class schools, although they see many places beyond the London streets, can yet reap much advantage from the mode of instruction which I am advocating; and as the range of knowledge increases, so will some such means of illustration be forced upon teachers. The labour and expense of tracing a dozen diagrams on glass, in the way hereafter explained, is considerably less than that involved in drawing a single large diagram for the schoolroom wall. By this easy method the illustrations in any book can be roughly copied and rendered available for an entire class.

In the higher branches of knowledge the lantern can also give its help. Botany, zoology, and natural history generally can be illustrated by diagrams, photographs, and in many cases by natural preparations. The revelations of the microscope can be transferred to the lantern, and the most complex organisms can be seen clearly defined and magnified many hundred times their natural size. It is possible, too, to show by the lantern many interesting experiments in chemistry and electricity which cannot be shown to a large number of persons in any other way. Let me cite for instance the formation of crystals, which can actually be watched in progress, highly magnified, by the simple expedient of smearing a piece of glass with a solution of sal ammoniac and placing it in the lantern. There are several adjuncts which may be fitted to a first-class lantern which I have not space to notice in detail. With the lantern-microscope ordinary microscopic slides can be utilized, and tanks for containing the living denizens of our ponds and ditches may be employed. The marvels of polarised light may be demonstrated with the lantern-polariscope. By another special device called the ‘aphengescope’ and which is made to fit on the lantern, opaque objects can be thrown on the screen. It is possible, for instance, to utilize ordinary photographs or diagrams on card, to show the moving works of a watch, sections of fruit, and many other objects as explained in a subsequent chapter.

The lantern, at the time of exhibition, should stand firmly. It can, if it be a small one burning oil, be placed on a box standing upon a table. I myself prefer to place it on a photographic tripod-stand, and this I effect by screwing on to the top of the stand a base-board upon which the lantern firmly fits. For large lanterns, such as the lime-light biunial, a far more solid arrangement is requisite. My own method is this. The lantern screws on to the top of its travelling-box, at the lower corners of which are sockets to admit four wrought-iron legs. These legs are bent outwards, and what I may call their toes are turned out, and have a hole into which a screw may be inserted and driven into the floor. The lantern is fastened to the box by two hinged pieces at the back, so that the nozzles

can be raised to any extent desired.

THE LIME-LIGHT.

The lime-light consists of a jet of mixed hydrogen and oxygen gases under pressure, ignited, and forced upon a cylinder of lime, which it renders white-hot. The heat given by these gases is second only to the heat of the electric arc, and will melt that most refractory of metals, platinum. Even the lime block cannot withstand the great heat to which it is exposed, but is quickly pitted under the action of the flame. Hence lime-light jets are furnished with an arrangement by which the lime cylinder can be turned at frequent intervals, so as to offer a fresh surface for the gases to play upon.

There are three kinds of jet used for the lantern. Firstly, a jet in which a stream of oxygen is forced through the flame of a spirit-lamp on to a cylinder of lime. This form is perfectly safe, and although it presents an immense improvement upon any form of oil arrangement, does not afford sufficient light to illuminate a screen more than about nine feet in diameter. Secondly, there is what is known as the blow-through jet. In this case the jet is connected with the house gas, and the oxygen meets it at the point of ignition, and is _blown through_ it on to the lime. This form of jet is also safe; indeed, it is often called ‘the safety jet,’ and affords plenty of light even for professional use. It is the one that I recommend the amateur to work with. Thirdly, there is the mixed jet, in which the two gases in separate bags are both under pressure, and mix together before reaching the external orifice. This form of lime-light gives the most light of any; but such care is requisite in dealing with it, that I shall say no more about it, considering it unfit for casual acquaintance.

A beginner might fancy that it would be a simple thing to mix the two gases in one bag, put it under pressure, and use them thus. So it would, and a beautiful light would be the result. Probably a beautiful explosion would be another result, for the two gases mixed form a most terrible compound, and a bag so charged would be almost equal in danger to a live shell.

With the spirit jet, or the ‘blow-through,’ the operator need have no fear of danger. Oxygen is not an explosive, and, although the best supporter of combustion, is not itself capable of being ignited. The spirit jet I should not recommend, except in situations where coal gas is not obtainable, so in my directions for using the lime-light, let it be understood that I am considering the employment of the blow-through, or safety jet.

Let us suppose, then, that we are preparing for an exhibition. The gas is made, and is at hand in the gas-bag; our lantern--and I will, for simplicity’s sake, consider it a single lantern only--is raised on its stand-table, or other support, at a convenient height from the ground, and we wish to have a private rehearsal in order to see that all is right. The first thing is to attach the hydrogen terminal of the jet, marked H, by flexible tubing to the nearest gas-bracket. Now take a cylinder of lime from its box, clear out the hole in the centre with a bit of wire, or a match, and place it on the pin provided for it above the jet. See that it turns freely, and so adjust the pin that the lime is distant from the jet nozzle about the sixteenth of an inch. Light the gas, and turn it down so that the flame is about an inch high. This can be done with advantage an hour or more before the lantern is really required, for the lenses and body of the lantern will by this means get thoroughly warmed, and any moisture upon the glasses, which would show as a blemish on the sheet, will be removed.

In all cases the hydrogen should be lighted first, if only to thoroughly warm the lime. Now the oxygen-bag can be put between the pressure-boards, and connected by another tube to the tap marked O. A half-hundred-weight having been put on the boards, the gas-bag tap may be turned on to the full. We may now attend to the jet. Turn on the hydrogen so that it flames up some inches over the lime, then gradually turn on the oxygen. At first it is air only that comes away, but presently with a characteristic little snap the two gases come together, and the brilliant lime-light is produced. A little care in adjustment of each tap alternately will soon show us the amount of gas from each which will give the best result.

It will soon be apparent to the operator that the spot of light on the lime must be exactly in the axis of the system of lenses, or the effect upon the sheet will be spoiled. The vertical movement of the jet is governed by a little screw, which holds it to the post on which it is fixed, which post stands upon an iron tray gliding between grooves. We must raise or lower the jet until the right place is found, when the screw can be brought home, and the jet is fixed. Even now, most probably, we shall find that the outer margin of the disc is ill-defined. This shows that the light is either too near or too far from the condenser. By moving the jet on its tray bodily backwards and forwards, we shall soon be able to find its correct position, and when found, that position will hold good to the end of the exhibition. We can now put a picture on the slide-stage, and focus it by means of the screw on the front lens. If the lime is properly adjusted and centred, our picture will be illuminated equally well in every part.

DISSOLVING VIEWS.

So far, we have considered the production of a brilliantly illuminated picture with a single lantern. For many years after the lime-light came into use, this was all that was required of it. But suddenly the beautiful effect known as dissolving views was contrived--an effect which, at the time of its introduction, made a wonderful sensation--and the method of producing which was for a long time kept secret. The old way of dissolving one picture into another, and the way which must still be adopted if oil-lanterns are in question, was to use two lanterns, side by side, and by a kind of see-saw arrangement in front of the lenses, to gradually uncover one nozzle whilst the other was being closed. This was easily done by furnishing each end of the see-saw with a screen of tin, the edge of each being cut into teeth like a comb. The one picture was thus caused to mingle with the other until the first lantern was quite closed, when the new design became perfectly disclosed. It soon became evident that the same effect could be produced more simply and economically with the lime-light lanterns, by contriving a special form of gas-tap which would slowly turn off the gases supplied to one lantern, while it as slowly admitted the gases to the other. By this arrangement nearly half the gas supply is saved, and therefore very little more is wanted for a dissolving-view apparatus than for a single lantern.

Dissolving view, or biunial lanterns, as they are generally termed, are now made in very compact form. The two systems of lenses, one above the other--not side by side as of old--are fitted into one mahogany case, lined with tin, and furnished with doors, so that the lights can be tended when necessary. At the back of the arrangement is placed the dissolving-tap, which is connected by indiarubber tubing with the lime-jets, and has two nozzles by which the hydrogen and oxygen respectively can be supplied to it. The dissolver is also furnished with by-passes, so that when the gases are turned from one lantern, just sufficient remains to keep the jet turned down ‘to the blue.’

The management of a pair of lanterns like this is, of course, much more onerous than that of a single lantern; but when once understood presents no difficulty. Before lighting up, be quite sure that all connections--and there are many--are quite secure, and that each place where indiarubber tubing fits on to metal is secured with twine. Now light the hydrogen in both lanterns, which you can do by placing the dissolving-tap in an upright position. Move the dissolver until the upper jet seems on the point of going out; but prevent it doing so by opening the hydrogen by-pass, and adjust this little tap so that the flame remains about one inch high when the other lantern is being used. Move the dissolver backwards and forwards a few times, so as to see that it works well, and that the hydrogen flares up in each lantern alternately.

We can now pay attention to the oxygen supply. First see that the bag is properly adjusted between the pressure-boards, and that the weight--one 56 lb. weight is sufficient to begin with--is in its place, above the upper board. Attending to the lower lantern first, turn up the hydrogen, and very gently admit the oxygen by turning the tap attached to the jet. When the light has been satisfactorily established, the oxygen by-pass must be turned in the same way that the other by-pass was just now treated, so as to admit a small amount of gas passing to the lantern not in use. If this be not done, the sudden inrush of the oxygen is sure to cause a small explosion, which will blow the light out. This does not indicate any danger whatever, but is inconvenient and undesirable during an exhibition. The upper lantern may now be attended to with the same precautions; and if all has been done well, the light will move from jet to jet alternately, as the dissolver is worked.

In using a double lantern, it is necessary to make both pictures coincident on the sheet. If one picture overlaps the other at every change, it has a most slovenly appearance. Such an error can be avoided by manipulating certain screws fitted to the metal front of the lantern, by which the two discs thrown upon the sheet can be adjusted until they quite coincide. These screws allow the lower nozzle to be pointed slightly upwards, and the upper one to point downwards, so that the images cast by each may be made to meet at the screen.

The double lantern is mainly employed for dissolving views; but its use does not stop here. A great many beautiful “effects” can be compassed by its means, a few of which I may here describe. Statuary slides form very beautiful pictures if photographed direct from the marble; but their effect is much enhanced if, by means of the auxiliary lantern, a glow of colour is thrown upon the screen at the same time. A few squares of differently tinted glasses, each mounted like an ordinary slide, with a mask of oval or round shape, are all that is needed. Again, a wintry scene in one lantern may be much improved by the effect of falling snow, produced by working a special form of slide in the other lantern. This slide consists merely of a frame containing a roller at the top with the handle projecting outside. As the handle is rotated, a long ribbon of black paper pierced with needle-pricks is rolled up upon it, and each prick makes a descending spot of light upon the screen, which together look exactly like falling snow. Sunset and moonlight effects, windows lighted up in night-scenes, ripples upon water, can all be managed by specially-devised ‘effect’ slides in the

second lantern. These effects can be much extended when a triple lantern is employed; but as this instrument is not often found--out of the hands of professional operators--we need not further allude to it.

But the double lantern can be used with great advantage from an educational point of view, in a manner that was first suggested by the present writer. I mean in the demonstration of the main features of Spectrum Analysis. Let me cite one example. A slide prepared and coloured so as to represent the continuous solar spectrum, marked with the principal _Frauenhofer_ lines, is placed, say, in the lower lantern. We now wish to show the bright lines given by an incandescent metal, say _sodium_. A slide, all blackened out but the double D line due to sodium, and so placed on the glass that it will exactly register with the D line in the coloured spectrum slide, is placed in the upper lantern. The dissolver is now brought into play, and can be so adjusted that while the continuous spectrum has all but faded away, the two brilliant sodium lines stand out boldly in their proper place. The spectra of all the other metals can be treated in exactly the same manner, keeping the continuous spectrum in the lower lantern for constant comparison and reference.

MAKING OXYGEN GAS.

There is very little danger incurred in the use of the lime-light if only the operator be intelligent in its employment. But there are certain dangers connected with the preliminary making of the oxygen gas, so that that part of the work should only be entrusted to a careful worker, and one who, knowing where the greatest care is required, will take every precaution against disaster. I have myself made several thousand feet of oxygen on different occasions, and have never yet met with any mishap; but as I know of cases where serious accidents have occurred, I have endeavoured to find out why they have happened, and I now consider myself forewarned, and therefore forearmed, against their repetition. The articles required for making the gas comprise a retort in which to generate it, a gas-stove to furnish the necessary heat, a wash-bottle or purifier, an indiarubber gas-bag, and several feet of tubing. Beyond these is wanted the mixture of chlorate of potash and peroxide of manganese in powder, which forms the charge of the retort, from which the gas is generated on the application of heat.

I have found that the best proportions of chemicals to use are four parts (by weight) of chlorate to one of manganese. Before being mixed together, both should be most carefully picked over, and most probably both will yield a small crop of bits of straw and wood-chips, which are not only injurious, but would in sufficient quantity prove actually dangerous if permitted to remain. The larger crystals of the chlorate, and any lumps which may be found in the manganese, should be rubbed down to powder by gentle pressure with the wooden spoon used for mixing the compound, about two pounds of which will yield sufficient gas for an evening's show. The mixture can now be funnelled into the retort, the nozzle of which, after being blown through to see that the passage is clear, can be screwed into its place.

The purifier, or wash-bottle, is made of tin, or may consist of a wide-mouthed bottle with an indiarubber cap, fitted with inlet and outlet tubes of metal or glass. In either case the vessel is three-parts filled with water, the inlet tube dipping some inches below the surface. This tube is subsequently connected by three or four feet of indiarubber tubing with the retort. As the gas is given off, it bubbles through this water, which not only cools it, but catches the particles of solid matter which are sure to be blown from the retort. The outlet tube is connected with the gas-bag. In the annexed illustration the relative positions of the retort, purifier, and gas-bag are shown, but in practice certain modifications are desirable. It is as well, for instance, to stand a chair between the retort and purifier, upon which the connecting rubber tube may rest, otherwise the water evolved from the crystals of potash will condense in the tube and obstruct the passage of the gas. Again, the gas-bag, instead of being on the same level, should be laid on a table, so that any water accidentally driven from the purifier may not be forced into it. The rubber tubes should have an orifice of nearly half an inch, and should on no account contain an inside coil of wire. Previous to making gas the bag should be warmed for an hour or so in front of a fire, so as to make it soft and pliable. The cock should then be opened, and the bag rolled tightly up so as to expel any air. The tap should then be closed.

[Illustration: FIG. 2.

Diagram showing relative positions of _g b_, Gas-bag; _w b_, Wash-bottle; and _r_, Retort.]

When all is ready, and every junction made except that between the bag and the pipe leading from the purifier, the gas-stove may be kindled, but turned down almost to its lowest point. If this precaution be not observed, the oxygen will come off with such rapidity as to be quite out of control, and will probably blow the connections away. In two or three minutes the gas will commence to bubble through the purifier, at first intermittently, but the bubbling will gradually become more regular, until it is evident that oxygen is

coming over in earnest. The brightening of a spark at the end of a blown-out match, held to the end of the purifier-tube, will announce the fact that all the air has been driven out of the pipes, and that gas has taken its place. Now is the time to connect the gas-bag with the purifier. With a quick movement the indiarubber tube should be slipped over the nozzle of the bag with one hand, while the tap is turned on with the other. The gas should now come over regularly until the bag is nearly half full, and this will occupy about fifteen minutes. The action will then probably flag a little, when the flame feeding the stove may be increased. When the bag is nearly full the flame can be raised, if occasion should require, to its utmost.

Some care is requisite in finishing the operation. When the bag is quite full and as tight as a drum, it should be disconnected before anything else is done. Of course at the moment of taking the tube from it, the tap must be turned. The next thing is to detach the retort from the purifier _before the gas is extinguished in the stove_. This is a most important point, for if the retort were cooled by putting out the gas first, the water might be sucked into the retort from the purifier, and a small steam-boiler explosion would be the result. In an hour or so the retort will be cool enough to handle, when the nozzle can be unscrewed and the vessel washed out with several changes of hot water. It can then be dried and put away for the next occasion. The retort-nozzle and its indiarubber tube should also be washed out, or it may get clogged.

Particular care must be taken to purchase the chlorate and manganese of some reliable dealer. Accidents have been reported owing to lamp-black, bone-black, etc., having been supplied in error for the manganese, which is a black powder much resembling them. I find that the best plan is to buy several pounds of each at a time, and to test a small quantity of the mixed ingredients in a test-tube over a spirit-flame. If the gas comes off with a slight sparkling of the ingredients all is right; but if there is anything approaching to an explosion, the manganese is at fault. One accident which I heard of was due to connecting the retort to the wrong side of the purifier; the gas had no outlet, and the retort exploded, breaking all the windows of the room in which it was.

Retorts are made either of copper or iron. I have tried both, and much prefer the latter, which have also the advantage of being cheaper than the copper ones. A good retort should serve for at least fifty charges, and even then a new bottom can be put into it, and it will do duty for another fifty. But no retort will last long unless properly treated. I am quite satisfied that the spent charge if allowed to remain has the effect of eating into the metal; it should, therefore, be washed out soon after use. The thickness of a retort after much use can be gauged by tapping it with the back of a knife when empty.

The oxygen gas is most usually stored in an indiarubber bag. These vary very much in quality, and the cheapest kinds are to be avoided. The rubber should be soft and pliant, and should be covered outside with stout twill. A good bag will almost last a lifetime if it be only used occasionally. I have had one for many years, which looks shabby enough with constant use, but seems to be as gas-tight and as efficient generally as the first day I had it. Even then it had been in use for some months by a friend.

[Illustration: FIG. 3.

Iron bottle for compressed oxygen gas.]

A bag full of gas is not the most portable thing that could be named, and various attempts have been made to replace it by some contrivance of a more convenient character. There is, too, the danger of accidental injury, which can readily occur if the bag is carelessly handled. In very cold weather, for example, some bags get quite stiff and hard, and have to be almost thawed before they can be used. Neglect of this precaution will lead to cracks, which will eventually turn into holes. Metal gas-holders--miniature copies of the big reservoirs seen at gas-works--which serve as travelling-boxes for the rest of the apparatus--are recommended by some, but are seldom used. Perhaps the most convenient arrangement--which, however, is only suitable for a single lantern--is to employ an iron bottle in which the oxygen is greatly compressed. Such a bottle charged with gas can be obtained from several dealers, and I have had some little experience of their use. A bottle measuring three feet in length, and about seven inches in diameter, will hold about eight feet of compressed gas--sufficient for an ordinary evening's work. At the end of the bottle is an opening closed with a tap which can only be opened by a special form of key. Into this orifice is screwed a nozzle, upon which an indiarubber tube can be readily fitted. When a bottle of this kind is used, the amount of oxygen which reaches the lime must be directly controlled by this tap, and not by the tap attached to the jet, which must remain fully opened. The reason of this is that the gas issues with such force, that, unless controlled in the way I have stated, it will blow off the tubing by its pressure. I found it so difficult to regulate the supply, that I had an independent screw-tap made to fit on to the bottle. This screw-tap is of the same pattern as those used on steam engines to control the supply of steam to the cylinder, and with it I can adjust the oxygen supply with the greatest nicety. My chief objections to the bottle system--which presents many advantages in the matter of portability--are, firstly, that you cannot charge the bottle yourself--it must always go back to the dealer for that purpose--and you are therefore

dependent for one of your first requisites upon others; and secondly, you do not know how much gas you are using, for you cannot see it diminish as you can when you employ a bag. For these and other reasons I still prefer bags to store my gas, and shall continue to do so until some improvement comes about.

[Illustration: FIG. 4.

Gas-bag and pressure-boards.]

The gas-bag is wedge-shaped, and the thin edge of the wedge has in its centre a gas-cock for the entrance and exit of the gas. The object of the bag being in this form is, that it can conveniently be placed between the pressure-boards. These, in their simplest form, consist of two boards strongly put together--the size of the bag which is used--which are hinged together at one end. At the centre of this end, and between the hinges, is cut an oval opening through which the gas-cock is thrust. A shelf on the upper board serves as a support for the weights. At least two weights are required--one being sufficient at first, when the bag is full; the other being added later on when the pressure becomes reduced. The weighted gas-bag should always be placed as near the lantern as circumstances will allow--in order that it may be under the eye of the operator--and the tube from it which supplies the lantern should be guarded, so that it is not accidentally stepped upon.

The lime-cylinders are sold in air-tight tin canisters holding one dozen each. They are of two qualities--hard and soft. For work where large pictures are required--necessitating the use of the mixed jet with both gases under heavy pressure--the hard limes must invariably be used. But where only a small sheet has to be covered, and one gas only is subjected to the unusual pressure, the soft limes will afford perhaps a better light than the harder ones. Occasionally the lime, be it hard or soft, will split. In such a case it ought to be immediately replaced by a fresh one, otherwise the flame may possibly be diverted towards the condensing lenses, and will fracture that nearest to the light. It is advisable always to keep a spare lime within the lantern, lying on the tray to which the jet is attached. By this means it gets warmed, and ready for use if required. Lime is most absorbent of moisture, and will, if kept where air can get to it, swell to double its former size, and finally crumble to powder. For this reason the tin canister containing the cylinders should have stretched over it, when once opened, a broad indiarubber band which will cover the junction between lid and box. If this precaution be neglected, the limes will swell with a force sufficient to break the tin-containing vessel asunder. A compressed lime cartridge, to which water is applied by artificial means, has lately been successfully introduced to supersede explosives hitherto used for mining purposes. This will show the immense power of expansion of which the substance is capable.

THE SCREEN OR SHEET.

And now a word about the best form of screen or sheet for showing lantern pictures upon. The best possible form of surface is a smooth whitewashed wall; but as this is not commonly found among the appointments of a sitting-room, where the lantern will be wanted, we must find some substitute which will most nearly resemble it. A sheet of cartoon paper, which can be bought of any length, and measuring more than four feet across, will do well if only a small disc is desired. The paper can be rolled up out of the way at a minute’s notice. If a larger screen is wanted, it can be made of stout calico, faced with white paper, and can be made to roll up and down like a school map of large dimensions. A map-mounter, or even an upholsterer, would soon rig up such an arrangement.

There is a very effective way of showing small pictures and diagrams with an oil-lantern, which I have more than once adopted, where a room has been long in proportion to its breadth. This is to make a wooden frame just large enough to take the full width of a sheet of tracing-paper, and to put this screen between the lantern and the spectators. Tracing-_cloth_ should be avoided, as it is so transparent that the light streaming from the lens makes a blotch in each picture when seen through it.

If the lantern is brought into regular use--in a schoolroom, for instance--it might be thought worth while to have a canvas sheet whitewashed, and hung in the same manner that a stage drop-scene is fixed. In making such a screen, the canvas should be tacked on a frame, and should have a coating of thin glue, which should be allowed to dry before two or more coats of whitewash are applied. It will be understood that a really opaque screen, such as this represents, is the more effective, because the light, instead of being partly lost--as it must be in penetrating an ordinary calico sheet--is reflected and utilized.

But for public exhibitions on a large scale, the calico sheet is the screen commonly in vogue, for it is conveniently put up and taken down, and can be rolled into a bundle for easy transport. A sheet properly hung should be as flat as a board and perfectly free from wrinkles of any kind, and this can be accomplished without much difficulty by adopting the following method, which is applicable to

screens from twelve feet square upwards.

[Illustration: FIG. 5.

Showing method of hanging a sheet.]

The sheet should have at its top edge a strong cord sewn into its hem, which cord should terminate at each side with a loop. On its sides and bottom edges, the sheet should have brass curtain rings sewn on to it at intervals of two feet. Having chosen the position of the screen, a couple of screw-eyes are screwed into the roof, or cornice near the top of the hall, at such a distance apart that the sheet can easily go between them. Through each of these screw-eyes is passed a thin, strong line, having at its end a clip like that commonly attached to a dog's chain. This clip is to clutch the loop of rope on each side of the sheet. The sheet can now be pulled up into position: the free ends of the cord being fastened to screw-eyes in the floor. It now merely remains to lace with string the curtain rings on the side of the sheet to the adjacent cord, and the arrangement is complete. The annexed diagram shows the upper corner of such a sheet, with its attachments, as just explained. Where the hall is of such a height that this plan is not available, or where the stern custodians faint with horror at the thought of their walls or ceilings being pierced with a screw-hole, the same method can be carried out by fastening the screw-eye to a timber upright on each side, supported by light struts.

Some persons prefer a sheet stretched on a frame, and such a frame of a very portable character can be easily devised. The frame itself is best made of lengths of pine, about the size of broom-handles. These can be joined together so as to make a frame of any reasonable dimensions, by six-inch lengths of brass tubing. The same tubing, mitred into L-pieces, will serve for the four corners. The sheet is furnished with tapes to secure it to the frame, and the woodwork is kept in an upright position by strong cords fastened by screw-eyes to the floor. The appearance of such a screen is much enhanced if the plain woodwork be hidden by a little drapery in the shape of narrow curtains at each side, and festoons of the same material above.

PICTURES FOR THE LANTERN.

Before the advent of the art of photography, pictures or slides for the lantern were traced on glass and painted by hand; and this art was carried to very great perfection. But no handiwork can equal the productions of the photographic camera; so that when it was found possible to produce transparent positives on glass, that could be magnified on the sheet to any extent without deterioration, the occupation of the artist on glass was almost gone. Photographs are now almost exclusively used, and form, when properly executed, the finest pictures for lantern use. The manner of their production is fully described in my little book 'How to Photograph;' but as there may be many would-be lanternists who do not care to dabble in photography, I will here give a few plain directions by which lantern slides can be extemporised.

The standard size for lantern pictures is 3¼ × 3¼ inches. The glass chosen should be as thin as possible, and quite free from scratches, bubbles, or flaws of any kind whatever. Remember that a piece of the finest hair which may well be overlooked upon the slide itself, will appear on the screen as a huge snake. In like manner a tiny bubble in the glass is magnified into a blemish the size of a soup-plate. Glass presents a very difficult surface to draw or paint upon, particularly if water-colours are employed, but by coating it with a transparent medium in the first instance the difficulty is much reduced. A film of plain collodion will, when dry, give a surface that can be easily sketched upon with a fine pen and Indian ink. The sketch so made can afterwards be filled in with water-colour, tempered with prepared ox-gall, and taking care that the colours used are those which are naturally transparent. Prussian blue, indigo, lake, the madders, gamboge, burnt and raw Sienna, Vandyke brown, are all transparent pigments, and will answer every purpose. Mixed with one another in the manner detailed in any manual of water-colour painting, greens, purples, and all secondary and tertiary tints are readily obtainable.

Another method, and an easier one, for producing lantern slides was introduced some years ago by the Rev. W. H. Dallinger; and although the author of the method intended it for drawings of microscopic subjects only, and with that idea brought it before the notice of the Royal Microscopical Society, it will be readily seen that it is adapted to all manner of lantern pictures. This method is best described in its inventor's own words: 'On finely ground glass drawing with a black-lead pencil is as easy as drawing upon cardboard. I get squares of glass to suit the size of my lantern carefully ground on one side like the focusing-glass of a camera.' The author goes on to describe how, by sketching upon the finely ground surface with a well-pointed hard pencil--HH or HHH--and shading with a softer one, such as HB, capital effects can be obtained. 'If it be necessary to put in colour it may be done, cleanly and carefully over the shading; thus one layer of colour suffices. Now, of course, although we have a perfect drawing of the object, with all the detail accurately given, it is not a transparency. But we can easily make it one. Thin some good pale Canada balsam

with benzine to about the consistency of cream, and simply float it over the ground surface of your glass; pour off until the drop comes very sluggishly. Then reverse the glass so that the corner from which the balsam was flowing off be placed upwards. Let the return flow reach about the middle; then reverse it again, and move it in several directions to get the balsam level. This may be done with a very little practice, so that the surface shall be undistinguishable from glass. We have now a perfect transparency. All that is required is twenty-four hours for hardening (keeping the glass level), and then another square of glass fastened on to it by strips of paper at the edges, with small pieces of card at the corners to prevent contact, and it makes an admirable lantern transparency.'

A hint about giving a fine grain to glass will not be out of place. Upon a perfectly flat and firm table lay a piece of glass say six and a half inches square, for this size can afterwards be cut across into four lantern pictures. A sheet of wet blotting-paper under the glass will keep it steady. Now pour upon its surface a mixture of flour-emery and water. Place another piece of glass above, and work it round with a circular motion, constantly spooning up the mud formed by the emery and water, and which oozes out between the glasses, and replacing it between them. In a short time both glasses will be beautifully ground on the surfaces which have been rubbed together. A moment's consideration will show that the ground effect is produced by the surface being broken up into innumerable tiny pits, each one of which scatters the light. By Mr. Dallinger's method of filling up these pits with a glassy medium like Canada balsam, the glass is once more presented with a flat surface, and therefore becomes once more transparent.

By whatever means the picture is produced the operator should have a glass transparent easel to work upon placed at an angle of forty-five degrees, with a sheet of paper underneath it to throw the light up through the glass he is drawing upon. A good easel can be made of a small frame--that belonging to a twopenny slate will do--attached to a base-board, and supported on each side by struts. A ledge of wood screwed across the frame makes a convenient support for the picture. The annexed cut will sufficiently explain the arrangements described.

[Illustration: FIG. 6.

Glass easel.]

And now a word or two about mounting the picture. As Mr. Dallinger points out, a cover-glass should be provided, but it should be prevented from actually touching the painted surface. This is best brought about by using the masks cut out of black paper, and sold for the purpose. A mask is inserted between the glasses, after which the whole is fastened together by pasting a slip of paper round the edges of the double glass, and turning it over on either side. Gum arabic with twenty-five per cent. loaf-sugar added, is a good medium by which to attach paper to glass.

[Illustration: FIG. 7. Masks for lantern slides.]

ON THE COLOURING OF PHOTOGRAPHIC TRANSPARENCIES.

There are many amateur photographers nowadays who can produce fair transparencies for the lantern, but at the same time there are many possessors of a lantern who know nothing about the 'black art.' Luckily for these, first-class pictures can be bought cheaply, their average price ranging from eighteenpence to two shillings each. Any optician's catalogue will show what an immense variety of subjects there is to chose from; not only can we obtain landscapes of nearly every part of the world, but we can purchase figure studies, copies of various pictures from books, maps, diagrams of scientific matters--micro-photographs and statuary. These slides if coloured are double the price of plain ones, and if very well coloured their price is quadrupled.

It would therefore be serviceable to many if they could learn how to colour such pictures for their own use, and I give simple directions how this can be accomplished. At the same time it is only fair to state that the work is really difficult, and anyone to attain even slight proficiency in slide-painting must devote a great deal of time and patience to the subject.

The photographic slide as sold consists of two glasses, one of which bears the photograph. This is separated from the cover-glass by a paper mask, the whole being bound round by a fillet of gummed paper. After carefully cutting round this fillet the two glasses may be separated, and the one bearing the picture is placed, varnished side upwards, upon the glass easel, ready for colouring. Some colourists speak in favour of water-colours for glass-painting, others prefer oil-colours, while some, I understand, employ both on the same picture. I have tried each system, and most certainly recommend oil-colours as being both easier to work with, and doing more satisfactory work into the bargain than water-colours.

The materials required comprise ordinary oil-colours in tubes, of which the following are perhaps the most useful that can be employed for the purpose:

Italian Pink. Raw Sienna. Yellow Lake. Chinese Orange. Brown Pink. Prussian Blue. Indigo. Neutral Tint. McGilp. Brown Madder. Rose Madder. Purple Madder. Crimson Lake. Burnt Sienna. Ivory Black.

It is curious to observe that the suitability of these colours for the particular purpose of glass-painting varies with the method of manufacture. I find by experience that one maker's Prussian blue is better than another's, while for a suitable crimson lake I have to go to quite a different shop, and so on.

The brushes used must be of the best, the majority of them being camel-hair, a few fine sables being kept for special touches. It is also necessary to provide some good large bushy camel-hair brushes to be used as softeners.

A flat porcelain palette is better than one of any other material, for the strength of the tints is seen well, and the surface can easily be cleaned with a little turpentine. A flexible palette knife must also be provided.

Dabbers to soften down skies and other flat masses of colour can be made by wrapping a ball of cotton wool in fine wash-leather. The leather should be first thoroughly washed with soap and water, and it will be better if a little of the soap be left in it as it dries, for this renders it soft and pliant. Both dabbers and brushes should be kept in a dust-tight box, for dust is the greatest enemy of the slide-painter.

It will be noticed that the list of colours given includes those only which are transparent, many others used in ordinary oil-painting being omitted. It is obvious that opaque colours like Naples yellow or chrome yellow would simply appear black on the sheet. The tyro who is used to other methods of painting, and has some idea of the harmony of colours, will, of course, have an immense advantage over anyone without artistic knowledge or feeling; and when he has once mastered the technicalities of the new work, will soon be able to produce passable pictures. The list of colours given is necessarily limited for the reason already given, but their number can be increased indefinitely by judicious blending one with the other. Let me give a few instances.

There is no green in the list given, simply because I do not know of a good transparent one. But various tints of green suitable for foliage can be easily made up with the colours named. Prussian blue mixed with any of the yellows will at once give a crude green, but it will not be suitable for use without the help of some other tint, such as burnt Sienna, or one of the reds. Italian pink and indigo make a fine green. Italian pink, brown madder, and Prussian blue is also another useful combination. Brown pink, indigo, and Vandyke brown will be found admirable for the shadows in foliage; indeed, the combinations for this purpose are endless. Again, there is a difficulty generally found in obtaining any approach to scarlet. The best I know of is a mixture of Italian pink, crimson lake, and Chinese orange. For browns, Vandyke brown, Chinese orange, ivory black, and burnt Sienna, will give any range of tints, from the coldest to the warmest. The reader will soon find by experiment the right proportions for mixing these colours to produce the desired effect, and he will be much assisted in the work by studying any good manual of water-colour painting. I recommend a water-colour manual in preference to one dealing with oil-colours, because the first deals more with transparent tints, which depend for their effect upon the white ground upon which they are laid. In like manner a lantern picture depends much upon the white surface upon which the tints are subsequently exhibited.

Our first attempt at glass-painting shall be an open landscape with figures in front--and we will suppose that the scene is laid in Britain. This would seem to some an unimportant point, until they remember that the skies and atmospheric effects seen in some other lands would require an altogether different treatment. I once coloured an Egyptian scene for a friend, and he admired my work, with one exception. 'You have given me an English sky,' he said. The sky will be the first thing to see to, and we will endeavour to give it a flat tint of blue slightly darker at the zenith than it is at the horizon. We squeeze out from its tube a little Prussian blue upon the palette, and dipping a good-sized camel-hair brush into a small cup of turpentine, we take up a little of the colour and work it about on the palette until it seems of the right strength. Before applying it to the glass we add to it a very small quantity of McGilp medium. Having mixed this last addition with our brush-load of colour, we can apply it to the glass, painting it in broad bands from side to side until the sky is all striped with blue. If the subject comprises a range of distant hills, let them too partake of the blue tint. When this is done, lay aside the brush and let the coloured glass rest for a minute, so that some of the turpentine will dry off. Now proceed to dab it carefully with one of the leather dabbers. With a very light touch bring the dabber down over and over again, and avoid anything like a rubbing action. The movement must be vertical, and not in the least horizontal. By bearing a little more heavily on the dabber as the horizon is approached, the tint will be sensibly lightened.

When this sky-colour has been uniformly dabbed in we may proceed to put in, or rather wipe out, some cloud effects. A little piece of soft kid wrapped round a pointed pen-holder is a good tool to use for the purpose, but a leather stump will answer the same end. This part of the work requires a little judgment and artistic taste. In a picture full of detail and which only has a small portion of sky exposed, it is best coloured simply blue. But where there is not much detail in the landscape, as in the case for instance of a mill on a bleak moor, the sky can be worked up with great advantage to the general effect. The clouds are wiped out by a rubbing action combined with a dabbing movement, so that the edges of the clouds formed remain quite soft. If they appear too hard they can be corrected by a few gentle dabs with the top of the finger. Before the leather is laid aside, it may be employed for wiping off any portions of colour which have accidentally been placed where they should not be. But if there is water included in the subject, such as a lake or river, it will when the sky is reflected in it partake of the same colour, and should be dabbed in at the same time.

We must now consider how we are going to treat the rest of our picture. If there is some expanse of foreground it will make the best contrast with the sky if we use a warm sandy colour. Chinese orange, raw Sienna, and brown pink mixed in various proportions to suit the lights and shadows of the picture will give the tint required. At this stage, too, the middle tints of the composition lying between the sky and the foreground can also be laid in. These will mostly consist of subdued greys, made up of Prussian blue, burnt Sienna, purple madder, and crimson lake. When these tints are all dabbed in, and the whole picture has been carefully gone over with the leather point, so as to remove truant colour, the slide may be laid aside to dry. I find it a good plan to have a tin box containing grooves for this purpose. The slides when grounded in in the way just described are placed in the grooves, and the open box is turned towards a fire. In an hour or so the colours are dry enough for further treatment.

We can now once more view our work on the easel, and most probably we shall see much to amend. The trees in the middle distance are too yellow, or too blue. They are easily corrected by a touch of the tint in which they fail. But at this stage of the painting we must use a different medium for our colours. We have done with dabbing, and must now lay the colours on as smoothly as possible with the brush alone. Canada balsam in turpentine, of the consistence of very thin varnish, is perhaps the best medium to use. It should be mixed with every colour as it is taken upon the brush.

The beginner will find some difficulty at first, particularly if oil-colours are new to him, in keeping his brushes in order. He need not have a brush for every tint. Let one be kept for skies, but only two or three others are necessary. When I commence to paint a batch of pictures I put on my table, after carefully dusting it all over with a damp cloth, a sheet of newspaper. In the centre stands my easel. On the left hand my colour-box, and on the right my palette. Close to the palette is placed a double thickness of clean white tissue paper, and a small pot of turpentine. When I wish to clean my brush, it is simply dipped in turpentine, and drawn over the surface of the white paper until I see that it leaves no trail of colour. By this simple means one brush can be used for any number of tints, for the cleansing of it does not occupy more than ten seconds.

It is in the foreground of a picture that the artist must be lavish with his bright colours. If the figures in the subject will allow of bright colouring, so much the better; but it must be remembered that if these colours are not put in with some regard to contrast, their effect is much diminished, if not altogether lost. Let the painter remember that the principal colours have their complementary colours, and that wherever we can place one of these tints against its complementary, we are bound to have harmony. Thus the complementary of blue is orange; of red, green; and of yellow, purple. But for further particulars of this nature, the aforesaid ‘Manual of Water-Colours’ must be studied.

When the picture is apparently finished, it will, most likely, require some finishing-touches. And here a new tool comes into use, namely, the etching-needle. Take a pointed piece of wood, about the size of a penholder, and bind upon it, by means of waxed thread, a good strong sewing-needle, leaving not more than a quarter of an inch of the point exposed. A few judicious touches with this needle will make a vast difference in the effect of a picture, but anything like coarse scratching must be avoided. The beginner will do well to view his work in the lantern as it gradually progresses, for what may look very well on the easel, will look very different when all its imperfections are magnified on the screen. The art of slide-painting is one which requires constant care and practice before anything like proficiency is attained.

In case some of my readers should be well acquainted with the use of water-colours, and may be deterred from trying the art of glass-painting because oils only are recommended for the work, I will briefly describe how water-colours are utilized for slide-painting. At the same time, I hold to my previously expressed opinion, that oil-colours are the more suitable pigments to use.

The varnished surface of a glass picture does not take kindly to water-colour, and as the brush is applied to it there is a repellent action which would make the painter despair if some means were not at hand to obviate the difficulty. By mixing each colour with a

certain proportion of prepared ox-gall the difficulty vanishes, and it is a wise precaution to rub a little ox-gall and water over the surface of the picture by means of a tuft of cotton wool, before any colour is applied at all.

The same transparent colours as those recommended for oil-painting may be employed, besides a few more transparent tints which are commonly not ground up in oil. But the dabbers are of a different description. Procure two or three good thick camel-hair brushes, and cut the hair off straight with a pair of scissors, so as to leave the ends of the hairs like a flat stump. Now carefully turn the brush round and round in the flame of a spirit lamp, or candle, so as to just singe the point of each hair. When this is done, rub the ends of the hair on the finest glass-paper until every trace of singeing has disappeared. This treatment will leave the brush with a flat woolly head like a mop, which makes an excellent dabber.

When the sky-colour has been applied as evenly as possible, and has been allowed to dry, the surface may be worked over with the dabber. But, before doing this, gently breathe over the colour. The dabber will remove little particles of the pigment, and will reduce the general strength of the tint, so that this loss should be provided for when the colour is first applied. Clouds, etc., can be wiped out with the leather, after the breathing operation, and in many other respects the two modes of colouring agree.

When the general tints have been laid in, the colours may receive a coat of mastic varnish, and this again can be worked over with colour to strengthen those tints which may require it. The varnish also confers a transparency upon the tints that they do not possess without it.

SHOWING SOLID & OPAQUE OBJECTS ON THE LANTERN SCREEN.

Those who are familiar with the working of the microscope know that the objects which are employed in that instrument can be viewed in two different ways. Transparent preparations have the light thrown through them by means of the adjustable mirror beneath the stage. Opaque objects, on the other hand, must have light thrown upon them from above, and this is managed by means of a separate condensing lens. For the magic lantern, transparent pictures are almost wholly employed; but there is a means of utilizing paper prints, photographic _cartes de visite_, and a certain limited number of solid objects, so that they may be shown in an enlarged form on the sheet. The effect is not so bright as when transparencies are employed, for a large proportion of the available light is absorbed in the operation; but there are many who would sacrifice a good deal in the way of effect, for the undoubted advantage of being able to utilize the contents of their albums, etc.

[Illustration: FIG. 8. Ground-plan of Chadburn’s Opaque Lantern.

_p_, Picture; _c_, Condenser; _l_, Light; _r_, Reflector; _o_, Objective.]

The first instrument which was constructed to accomplish this end is known as Chadburn’s lantern; and, as will be seen from the annexed diagram, it differs very much from the ordinary form of magic lantern. From what has been already said concerning the loss of light, it will be evident that a powerful luminant is a matter of prime consideration. A good oil-lantern will do the work--but not so well as the lime-jet. The luminous face of the lime, instead of being turned towards the optical system, is opposite a concave reflector placed at the back of the lantern. From this the light is reflected towards the condenser, which condenser concentrates the light obliquely upon the object. The picture or object is contained in a kind of box joined to the main lantern, and which holds immediately opposite the illuminated picture the lens for projecting its image upon the screen. This pioneer form of opaque lantern has been superseded by the instrument called the Aphengescope. This can be purchased now of most opticians. Virtually it consists of the front chamber of Chadburn’s lantern constructed to fit on to the front of any ordinary oil or lime-lit lantern.

The aphengescope can be used for showing woodcuts, paper photographs, printed and written matter of any kind, so long as the space covered is within the size of the instrument. Thus any caricatures from our comic publications could be pasted on card, and enlarged by its means. But it will be readily observed that this class of subjects, if photographed as transparent positives and used in the ordinary lantern, can be shown far better. The principal use of the aphengescope is to show solid objects which cannot by any possibility be shown enlarged without its help.

Let us suppose, for instance, that it is desired by some collector to show his friends a cabinet of coins and medals. Such objects are so bright in themselves that they are admirably adapted to this instrument. Their form, colour, and minute markings are faithfully reproduced; whilst the raised portions catch the reflected light in such a way as to make the images look as solid as the objects themselves. At the Polytechnic Institution, a lecture upon the invention of the watch, and its gradual development, was beautifully illustrated by the opaque lantern. First came the different parts of the watch, and then the varied movements. It was most curious

and instructive to see the wheels and springs all in movement upon the screen.

There are also many natural things which can be shown by the same means. A freshly opened oyster makes a very remarkable object. A still more curious effect is obtained by concentrating the light upon a freshly cut orange or lemon. When the fruit is squeezed, the pips and juice appear to fly upwards; for, of course, everything is shown upside down, as in the ordinary lantern. The opaque lantern was once introduced into a court of law in America, as a witness for the prosecution in a case of forgery. The following is a condensed account of the occurrence, taken from a New York paper:

‘During the recent trial, it became necessary to show the differences between a genuine signature and an imitation or forgery of the same. For this purpose, there was brought into court a powerful reflecting magic lantern. The room was darkened, and images of the two signatures, enormously magnified, were thrown side by side upon a screen before the judge and jury. The false signature was at once revealed. The illumination of the writing was effected by means of two powerful lime-lights contained within the lantern. The peculiar arrangement of the lights and screen enables the examiner to discover the surface of the paper through the ink, so that patching, shading, or painting of letters becomes evident the instant it is brought under the focus of the lantern. An arrangement of screens, by which the light is cut off alternately from either side of the instrument, discovers any tampering with the surface of the paper, either by scratching or washing by chemicals. (In other words, by throwing the light alternately from either side, the relief caused by the grain of the paper is clearly shown; and any tampering with that relief, by scratching or otherwise, at once becomes apparent.) The instrument, in this case, was of sufficient capacity to view at once two bank-notes placed side by side, and the pictures were of such fineness that there was no difficulty in viewing their smallest details. I fear that the introduction of a magic lantern into an English court of law would be rather too sensational for the ordinary legal mind--particularly as the evidence of an expert, with the help of a microscope, would answer the same end.

Under the name of the Physioscope, an immense opaque lantern was exhibited some years back in London. The object magnified on the sheet was the human face, and a correcting lens was included in the apparatus, so that the face was seen right way up. It was always rather an unhappy face, for the individual who lent his countenance to the transaction had on either side of him, and within a few inches of his cheeks, a very powerful lime-light, the heat and glare from which were sufficient to render anyone uncomfortable who was not a salamander.

THE LANTERN MICROSCOPE.

Of late years it has become possible to take very beautiful photographs of microscopic objects, which, when used as lantern-slides, give a very fine effect. Numerous slides of this character may now be purchased, which cover a vast field of microscopic knowledge, and many will be content with what they can thus obtain. But there is another class of workers who, perhaps possessing a large number of microscopic slides, will be glad to utilize them for the lantern, so that they are no longer limited to the individual eye. For these the lantern microscope, which will screw in front of the lantern in place of the usual optical system, is a most useful instrument. Different makers advertise in their catalogues lantern microscopes which range in price from twenty-five shillings to as many guineas. And it recently came to my knowledge that a well-known London optician has undertaken the construction of a few of these instruments at the price of £150 each. The amateur lanternist will, therefore, have some difficulty in deciding what he ought to pay for such an instrument. And it is most difficult to advise him on that point. His best plan is, perhaps, to see for himself what the makers can offer him, and, if possible, to seek a trial of the instrument before he purchases it.

The lantern microscope is a modification of the old solar microscope--an instrument which could be screwed against a hole in the shutter of a darkened room--and which had a mirror outside which projected a beam of sunlight through it. The objective lenses were uncorrected, and small in aperture, so that the instrument was far from being a perfect one. But the intensity of the solar light covered many objectionable features, and it was possible to get some astonishing effects with the contrivance. But sunlight is such an uncertain commodity in our climate that, when the lime-light came into prominence, the old solar microscope was forgotten in favour of that which depended upon a more constant, if a far less intense, light source.

The great difficulty to overcome in the lantern microscope is to get the light sufficiently intense to well illuminate the objects. The aperture of a microscope objective, even of low power, is so small, that, when the pencil of light which it emits is spread over a screen, the light is so attenuated that the details of the object are difficult to make out. In the near future, when we are promised that electricity shall be laid on to our homes, as gas is now supplied to us, the difficulty will disappear, for the electric-arc light is many times more intense than the most powerful lime-jet.

Having obtained a lantern microscope, the next thing to consider is the class of objects which can best be shown with it. To help the reader in determining this point, I will now give a kind of sketch of a popular lecture to accompany an exhibition of the instrument.

Such a lecture might usefully commence with a brief description of the microscope: its history, and how, in its improved form, it has opened up a world of minute life, of which our forefathers could have had no conception. We might then put forward a few remarks as to the adaptation of the microscope to the oxyhydrogen lantern, and point out how by its aid a number of persons can at the same time see what, in an ordinary microscope, is visible to only one person. So much by way of introduction.

We might next enlarge upon the circumstance that the contents of the world have been classified into three general divisions--popularly known as the three kingdoms of Nature: the Mineral Kingdom, the Vegetable Kingdom, and the Animal Kingdom. Show how one is dependent upon the other, and the difficulty in many cases of drawing a line to separate the minute organisms of the Animal Kingdom from those of the Vegetable World. Numerous examples from the lower forms of life may be quoted to illustrate this. Now show and explain subjects from each of the three divisions, taking the minerals first. Define a mineral, and show how they crystallize in definite forms. Illustrate the process of crystallization by putting a drop of a saturated solution of sal-ammoniac on a slip of glass, and spreading it over with a brush. Such a glass placed in the microscope will, as it dries, become covered with branches of crystals, which seem to grow and strike out in various directions on the sheet in a truly marvellous manner. Sections of various minerals may next be shown, finishing with sections of coal. In pointing out the origin of coal from plants, we may easily drift into the next division of our subject--the Vegetable Kingdom.

Here we have indeed a wide field to illustrate. Commencing from the simple cell, as exhibited, for instance, in a bit of so-called green mould, and arriving gradually at sections of different stems of plants (which by the way form most beautiful objects on the screen), sections of different woods, parts of flowers, etc. From these it will be easy to step over the indistinct boundary-line which separates us from the Animal World. Here we can commence with the lowest organisms; next show the living inhabitants of our ponds and ditches. Arrive at the Insect World, and show the generally unfamiliar parts of familiar insects--bees, wasps, flies, etc. We can then go higher, and exhibit sections of bone, hair, etc.; finishing with the structure of the human body, so far as it can be indicated by means of the microscope. This is a brief sketch of the kind of entertainment the microscope is able to afford, which can be modified to suit the views of the exhibitor.

MECHANICAL OR MOVING-PICTURES.

The most common form of moveable slide is that known as a ‘comic slip.’ This mechanical contrivance for the amusement of youth is generally of the coarsest execution, and it speaks little for the originality of our slide-producers that the same old things should appear in catalogues year after year with no improvement. The ‘comic slip’ consists of a glass in a wooden frame, with another loose piece of glass which can work backwards and forwards in front of it. This movable glass generally serves as a mere screen to cover something painted underneath it, and it is rubbed over with black varnish so as to be opaque. Thus a gentleman is represented with a nose of the normal size, but as the screen is withdrawn it elongates to an awful extent. Or a woman’s tongue may be graphically, if not elegantly, portrayed in the same manner.

In another class of slide a circular glass is kept in slow rotation in front of the slide proper by means of a rack-work attachment. A common design for this device is a landscape with a windmill in the centre. The sails of the mill are painted on the revolving glass, and can be kept in rotation as long as desired. The chromatrope effect is managed in the same way, only that in this case both glasses are caused to slowly revolve in reverse directions. There are many people who admire chromatropes, and many others who regard them as rather trying to the eyes. Rippling water, the rising or setting of the sun or moon, and astronomical slides illustrative of the movements of the heavenly bodies, are among the subjects which can be well illustrated by mechanical means.

Perhaps the cleverest piece of apparatus ever invented to give the effect of movement by means of a magic lantern is Beale’s choreutoscope. This instrument depends upon the well-known phenomenon common to our eyes, called persistence of vision. The image of anything that we look at is cast upon the retina at the back of the eye by the agency of the crystalline lens, which is placed behind the pupil. So far, the human eye resembles a camera obscura. Persistence of vision means that an image so cast upon the retina remains impressed there for about the eighth part of a second. For this reason we wink continually without knowing it, for the light impression remains with us during the short time that the eye is closed in accomplishing that necessary action. A burnt stick with a red-hot end whirled round and round appears to us like an unbroken circle of fire. The separate drops of rain as they fall from the sky look like streaks of water, and so an artist will represent them in his picture. A quickly moving meteor looks like a long trail of fire for the same reason.

In the choreutoscope we have a very elegant adaptation of the same principle. It consists, in its commercial form, of a slide arrangement that can be placed in any lantern. This contains a narrow strip of glass, with, say, six figures painted upon it, each figure having a different position. A dancing man is a good representative of the rest. By a turn of a handle each figure is brought into view successively, but so rapidly as to give the effect of moving arms and legs. An interceptor or screen runs in front of each figure as the change occurs.

One of the best designs made for this instrument is a dancing skeleton (see annexed cut). In this case the figures are cut stencil-fashion out of very thin brass, and the openings thus cut transmit so much light that the effect is far more brilliant than if the design were executed on glass in the usual manner. The choreutoscope is not only a most amusing contrivance, but it illustrates in a very beautiful manner this optical law called ‘persistence of vision.’

[Illustration: FIG. 9. Facsimile of a dancing skeleton for Beale’s Choreutoscope.]

CONCLUDING REMARKS.

The best lantern and the best pictures will not interest an audience unless the entertainer or lecturer is up to his work, and the matter which he conveys is skilfully put together. I believe that lecturing would be far more popular among us had it not been for the numbers of utterly incompetent men who have in past years bored audiences to such an extent that the word ‘lecture’ is to them as a red rag is to a bull. When I say incompetent men, I do not mean uneducated ones; but I mean those who from natural want of voice, and utter ignorance of its management, are generally unfit for public speaking. It seems to be too often conceded that because a man has written a book--or done something else which has brought him before public notice--he is, without any previous knowledge or practice, fit to lecture on the particular subject with which his name is identified. Or his claims to recognition as a lecturer are based upon certain cabalistic letters after his name, which in many cases represent only so many guineas yearly subscribed to those who confer them. Lecturing is an art that can only be acquired successfully by those who have certain qualifications for the work, and among these the foremost is the power of imparting knowledge to others in a common-sense and interesting manner. Luckily for him, the amateur lecturer is likely to meet with a far more indulgent audience than those which professional men have occasionally to face; but this is no reason why he should be careless as to his method of delivery, or of the matter delivered. Perhaps the er--worst fault er--which a lecturer can er--fall into--is the one indicated er--in this sentence. ‘To _err_ is human,’ in a wider sense, unfortunately, than Pope, the writer of that well-known line, ever dreamt of. Unless a would-be lecturer can conquer this tiresome habit, or any other trick of speech which he may have cultivated, by all means let him confine himself to the management of the lantern while some one else acts as showman.

If two people are thus managing an exhibition between them, and if the room be large, so that they are widely separated, some signal from the lecturer to indicate that he wants the next picture thrown on the screen becomes necessary. A bell, or anything that makes a noise, is distracting both to lecturer and audience. Still worse are verbal instructions from one to the other. I myself use an electric single-stroke bell with the gong removed, the hammer of which gives a little click unmistakable to the operator, but quite unheard by the audience. Such a bell can be placed close to the lantern, while its push is far away on the lecturer’s desk. Sometimes a string can be carried from lecturer to operator, a gentle pull of which will give the necessary signal. Some lecturers signal by uncovering a little pane of red glass in the back of their reading-lamp. But I think that any sight signal is inadmissible, because the operator has quite enough to do in attending to his duties without having his attention thus distracted. The signal, of whatever nature it be, should be given by the lecturer some seconds before he has finished with the picture in hand, otherwise there is an awkward pause while the operator makes the necessary change. Before the lecture begins, the reader should make himself not only thoroughly familiar with his subject, but should be also familiar with the different pictures which illustrate it. And this especially applies to the common case of those who have purchased or hired a set of slides and a published lantern reading--many of which are compiled by writers of repute, and are in every way excellent. Let him, then, carefully go through the reading beforehand, comparing each picture with the text, and making himself so familiar with its details that he is afterwards able, during performance, to point out anything to which attention may advantageously be directed. Particularly is this necessary in the case of an introductory map, where places of importance to the subject in hand must be pointed out. The most convenient form of pointer, by the way, is a Japanese fishing-rod, which telescopes into small compass when not in use.

For an evening’s lantern entertainment to be successful, a great deal depends upon the operator. With a mineral-oil lamp in a small room, his duties are not very onerous, for the lamp when once established should require no further attention, except it be to turn down a wick which shows symptoms of smoking. But he should be careful to have in reserve a glass or two to replace the front

glass of the combustion-chamber, which may crack through some unexpected draught of air. His slides must all be numbered and in order. They may be each mounted in a wooden frame to fit the lantern stage, or else the lantern may be fitted with a permanent grooved slide in which the glass pictures are placed one after another, the last one pushing out the one before. Another plan, which is a good one to adopt where a single lantern only is being used, is to make use of what is called a panoramic slide. It is constructed like the one just described, only it is furnished with a travelling tape upon which each picture rests. The turn of a handle moves the tape, and the pictures travel forward panorama-fashion.

In the use of a double lantern furnished with lime-jets, there is plenty for two hands to do, for the operator has to keep his attention fixed not only upon the business of changing the pictures, but upon the condition of the lights. As the pressure of the oxygen gas varies as it is gradually consumed, so the supply of the two gases to the jets will want constant adjustment if the maximum quantity of light is expected. Extra weights, too, must be added as the pressure-boards gradually sink down. Beyond carefulness in this respect, the lantern operator must see to the occasional turning of his limes, taking care to do this when the lime wanting attention is not in actual use. He should also find time to wipe the glass of each picture with a leather before putting it in the lantern, for a film of moisture condenses on the surface, particularly in a room full of people.

The success of a lantern entertainment depends nearly as much on the competence of the assistant as it does on the powers of the lecturer. I am perhaps fastidious on this point, for my lecturing apprenticeship was served at the late Royal Polytechnic Institution, where operators were employed who had spent the best part of their lives in this particular work. It was seldom, indeed, that they made a mistake.

THE END.

PREFACE TO THE FIFTEENTH EDITION.

Several new slide rules for special calculations are described in this edition, and the contents further extended to include a section dealing with screw-cutting gear calculations by the slide rule—an application of the instrument to which attention has been given recently.

Mention should be made of the fact that some of the special slide rules described in previous editions are no longer obtainable. As, however, the descriptive notes may be of service to those possessing the instruments, and are, in some measure, of general interest, they have been allowed to remain in the present issue.

The author tenders his thanks to the many who have evinced their appreciation of his efforts to popularise the subject; also for the many kind hints and suggestions which he has received from time to time, and with a continuance of which he trusts to be favoured in the future.

C. N. P.

WITHINGTON, MANCHESTER, _November 1917_.

PREFACE TO THE SEVENTEENTH EDITION.

The sustained demand for this very successful work having resulted in the early call for a new edition, the opportunity has been taken to introduce descriptions of new slide rules and to effect some slight revisions.

C. N. P.

WITHINGTON, MANCHESTER, _December 1920_.

THE SLIDE RULE.

INTRODUCTORY.

The slide rule may be defined as an instrument for mechanically effecting calculations by logarithms. Those familiar with logarithms and their use will recognise that the slide rule provides what is in effect a concisely arranged table of logarithms, together with a simple and convenient means for adding and subtracting any selected values. Those, however, who have no acquaintance with logarithms will find that only an elementary knowledge of the subject is necessary to enable them to make full use of the slide rule. It is true that for simple slide-rule operations, as multiplication and division, a knowledge of logarithms is unnecessary; indeed, many who have no conscious understanding of logarithms make good use of the instrument. But this involves a blind reliance upon rules without an appreciation of their origin or limitations, and this, in turn, engenders a want of confidence in the results of any but the simplest operations, and prevents the fullest use being made of the instrument. For this reason a brief, but probably sufficient _résumé_ of the principles of logarithmic calculation will be given. Those desiring a more detailed explanation are referred to the writer's "Logarithms for Beginners."

The slide rule enables various arithmetical, algebraical and trigonometrical processes to be performed with ease and rapidity, and with sufficient accuracy for most practical purposes. A grasp of the simple fundamental principles which underlie its operation, together with a little patient practice, are all that are necessary to acquire facility in using the instrument, and few who have become proficient in this system of calculating would willingly revert to the laborious arithmetical processes.

THE MATHEMATICAL PRINCIPLE OF THE SLIDE RULE.

Logarithms may be defined as a series of numbers in _arithmetical_ progression, as 0, 1, 2, 3, 4, etc., which bear a definite relationship to another series of numbers in _geometrical_ progression, as 1, 2, 4, 8, 16, etc. A more precise definition is:—The logarithm of a number to any base, is the _index of the power_ to which the base must be raised to equal the given number. In the logarithms in general use, known as _common logarithms_, and with which we are alone concerned, 10 is the base selected. The general definition may therefore be stated in the following modified form:—_The common logarithm of a number is the index of the power to which 10 must be raised to equal the given number._ Applying this rule to a simple case, as 100 = 10^2, we see that the base 10 must be squared (_i.e._, raised to the 2nd power) in order to equal 100, the number selected. Therefore, as 2 is the index of the power to which 10 must be raised to equal 100, it follows from our definition that 2 is the common logarithm of 100. Similarly the common logarithm of 1000 will be 3, while proceeding in the opposite direction the common log. of 10 must equal 1. Tabulating these results and extending, we have:—

Numbers 10,000 1000 100 10 1 Logarithms 4 3 2 1 0

It will now be evident that for numbers

between 1 and 10 the logs. will be between 0 and 1 „ 10 „ 100 „ „ 1 „ 2 „ 100 „ 1000 „ „ 2 „ 3 „ 1000 „ 10,000 „ „ 3 „ 4

In other words, the logarithms of numbers between 1 and 10 will be wholly fractional (_i.e._, decimal); the logs. of numbers between 10 and 100 will be 1 _followed by a decimal quantity_; the logs. of numbers between 100 and 1000 will be 2 followed by a decimal quantity, and so on. These decimal quantities for numbers from 1 to 10 (which are the logarithms of this particular series)

are as follows:—

Numbers 1 2 3 4 5 6 7 8 9 10 Logarithms 0 0·301 0·477 0·602 0·699 0·778 0·845 0·903 0·954 1·000

Combining the two tables, we can complete the logarithms. Thus for 3 multiplied successively by 10, we have:—

Numbers 3 30 300 3000 30,000 etc. Logarithms 0·477 1·477 2·477 3·477 4·477 „

We see from this that for numbers having the _same significant figure_ (or figures), 3 in this case, the decimal part or _mantissa_ of the logarithm is the same, but that the integral part or _characteristic_ is always _one less than the number of figures before the decimal point_.

For numbers less than 1 the same plan is followed. Thus extending our first table downwards, we have:—

Numbers 1 0·1 0·01 0·001 0·0001 etc. Logarithms 0 –1 –2 –3 –4 „

so that for 3 divided successively by 10, we have:—

Numbers 3 0·3 0·03 0·003 0·0003 etc. Logarithms 0·477 ■1·477 ■2·477 ■3·477 ■4·477 „

Here again we see that with the same significant figures in the numbers, the mantissa of the logarithm has always the same (_positive_) value, but the characteristic is _one more_ than the _number of 0's immediately following the decimal point_, and is _negative_, as indicated by the minus sign written over it. Only the decimal parts of the logarithms of numbers between 1 and 10 are given in the usual tables, for, as shown above, the logarithms of all tenfold multiples or submultiples of a number can be obtained at once by modifying the characteristic in accordance with the rules given.

An examination of the two rows of figures giving the logarithms of numbers from 1 to 10 will reveal some striking peculiarities, and at the same time serve to illustrate the principle of logarithmic calculation. First, it will be noticed that the addition of any two of the logarithms gives the logarithm of the _product_ of these two numbers. Thus, the addition of log. 2 and log. 4 = 0·301 + 0·602 = 0·903, and this is seen to be the logarithm of 8, that is, of 2 × 4. Conversely, the difference of the logarithms of two numbers gives the logarithm of the _quotient_ resulting from the division of these two numbers. Thus, log. 8 – log. 2 = 0·903 – 0·301 = 0·602, which is the log. of 4, or of 8 ÷ 2.

One other important point is to be noted. If the logarithm of any number is _multiplied_ by 2, 3, or any other quantity, whole or fractional, the result is the logarithm of the original number, raised to the 2nd, 3rd, or other power respectively. Thus, multiplying the log. of 3 by 2, we obtain 0·477 × 2 = 0·954, and this is seen to be the log. of 9, that is, of 3 raised to the 2nd power, or 3 _squared_. Again, log. 2 multiplied by 3 = 0·903—that is, the log. of 8, or of 2 raised to the 3rd power, or 2 _cubed_. Conversely, dividing the logarithm of any original number by any number _n_, we obtain the logarithm of the _n_th root of the original number. Thus, log. 8 ÷ 3 = 0·903 ÷ 3 = 0·301, and is therefore equal to log. 2 or to the log. of the _cube root_ of 8.

Only simple logs. have been taken in these examples, but the student will understand that the same reasoning applies, whatever the number. Thus for 20^3 we prefix the characteristic (1 in this case) to log. 2, giving 1·301. Multiplying by 3, we have 3·903 as the resulting logarithm, and as its characteristic is 3, we know that it corresponds to the number 8000. Hence 20^3 = 8000.

In this brief explanation is included all that need now be said with regard to the properties of logarithms. The main facts to be borne clearly in mind are:—(1.) That to find the _product_ of two numbers, the logarithms of the numbers are to be _added_ together, the result being the logarithm of the product required, the value of which can then be determined. (2.) That in finding the _quotient_ resulting from the division of one number by another, _the difference_ of the logarithms of the numbers gives the logarithm of the quotient, from which the value of the latter can be ascertained. (3.) That to find the result of _raising a number to the nth power_, we _multiply_ the logarithm of the number by _n_, thus obtaining the logarithm, and hence the value, of the desired result. And (4.) That to find the n_th root of a number_, we _divide_ the logarithm of the number by _n_, this giving the logarithm of the result, from which its value may be determined.

NOTATION BY POWERS OF 10.

A convenient method of representing an arithmetical quantity is to split it up into two factors, of which the first is the original number, with the decimal point moved so as to immediately follow the first significant figure, and the second, 10^{_n_} where _n_ is the

number of places the decimal point has been moved, this index being _positive_ for numbers greater than 1, and _negative_ for numbers less than 1.[1] In this system, therefore, we regard 3,610,000 as 3·61 × 1,000,000, and write it as 3·61 × 10^6. Similarly 361 = 3·61 x 10^2; 0·0361 (= (3·61)/(100)) = 3·61 × 10^{–2}; 0·0000361 = 3·61 × 10^{–5}, etc. To restore a number to its original form, we have only to move the decimal point through the number of places indicated by the index, moving to the right if the index is positive and to the left (prefixing 0's) if negative. This method, which should be cultivated for ordinary arithmetical work, is substantially that followed in calculating by the slide rule. Thus with the slide rule the multiplication of 63,200 by 0·0035 virtually resolves itself into 6·32 × 10^4 × 3·5 × 10^{–3} or 6·32 × 3·5 × 10^{4–3} = 22·12 x 10^1 = 221·2. It will be seen later, however, that the result can be arrived at by a more direct, if less systematic, method of working.

THE MECHANICAL PRINCIPLE OF THE SLIDE RULE.

[Illustration: FIG. 1.]

The mechanical principle involved in the slide rule is of a very simple character. In Fig. 1, A and B represent two rules divided into 10 equal parts, the division lines being numbered consecutively as shown. If the rule B is moved to the right until 0 on B is opposite 3 on A, it is seen that any number on A is equal to the coinciding number on B, plus 3. Thus opposite 4 on B is 7 on A. The reason is obvious. By moving B to the right, we add to a length 0·3, another length 0·4, the result read off on A being 7. Evidently, the same result would have been obtained if a length 0·4 had been added, by means of a pair of dividers, to the length 0·3 on the scale A. By means of the slide B, however, the addition is more readily effected, and, what is of much greater importance, the result of adding 3 to _any one of the numbers_ within range, on the lower scale, is _immediately_ seen by reading the adjacent number on A.

Of course, subtraction can be quite as readily performed. Thus, to subtract 4 from 7, we require to deduct from 0·7 on the A scale, a length 0·4 on B. We do this by placing 4 on B under 7 on A, when over 0 on B we find 3, on A. It is here evident that the _difference_ of any pair of coinciding numbers on the scales is constantly equal to 3.

[Illustration: FIG. 2.]

An important modification results if the slide-scale B is inverted as in Fig. 2. In this case, to find the sum of 4 and 3 we require to place the 4 of the A scale to 3 on the B scale, and the result is read on A over 0 on B. Here it will be noted, the _sum_ of any pair of coinciding numbers on the scales is constant and equal to 7. This case, therefore, resembles that of the immediately preceding one, except that the _sum_, instead of the _difference_, of any pair of coinciding numbers is constant.

To find the difference of two factors, the converse operation is necessary. Thus, to subtract 4 from 7, 0 on B is placed opposite 7 on A, and over 4 on B is found 3 on A.

From these examples it will be seen that with the slide _inverted_ the methods of operation are the reverse of those used when the slide is in its normal position.

It will be understood that although we have only considered the primary divisions of the scales, the remarks apply equally to any subdivisions into which the primary spaces of the scales might be divided. Further, we note that the length of scale taken to represent a unit is quite arbitrary.

THE PRIMITIVE SLIDE RULE.

The application of the foregoing principles to the slide rule can be shown most conveniently by describing the construction of a simple form of slide rule:—Take a strip of card about 11 in. long and 2 in. wide; draw a line down the centre of its width, and mark off two points, 10 in. apart. Draw cross lines at these points and figure them 1 and 10 on each side, as in Fig. 3. Next mark off lengths of 3·01, 4·77, 6·02, 6·99, 7·78, 8·45, 9·03 and 9·54 inches, from the line marked 1. Draw cross lines as before, and figure these lines, 2, 3, 4, 5, 6, 7, 8 and 9. To fill in the intermediate divisions of the scale, take the logs, of 1·1, 1·2, 1·3, etc. (from a table), multiply each by 10, and thus obtain the distances from 1, at which the several subdivisions are to be placed. Mark these 1·2, 1·3, 1·4, etc., and complete the scale, making the interpolated division marks shorter to facilitate reading, as with an ordinary measuring rule. Cutting the card cleanly down the centre line, we have the essentials of the slide rule.

[Illustration: FIG. 3.]

The fundamental principle of the slide rule is now evident:—Each scale is graduated in such a manner that the _distance of any number from 1 is proportional to the logarithm of that number_.

[Illustration: FIG. 4.]

“We know that to find the product of 2 × 3 by logarithms, we add 0·301, or log. 2, to 0·477, the log. of 3, obtaining 0·778, or log. 6. With our primitive slide rule we place 1 on the lower scale to 3·01 in. (which we have marked 2) on the upper scale (Fig. 4). Then over 4·77 in. on the lower scale (which we marked 3), we have 7·78 in. (which we marked 6) on the upper scale. Conversely, to divide 6 by 3, we place 3 on the lower scale in agreement with 6 on the upper, and over 1 on the lower scale read 2 on the upper scale. This method of adding and subtracting scale lengths will be seen to be identical with that used in the simple case shown in Fig. 1.

THE MODERN SLIDE RULE.

The modern form of slide rule, variously styled the Gravêt, the Tavernier-Gravêt, and the Mannheim rule, is frequently made of boxwood, but all the leading instrument makers now supply rules made of boxwood or mahogany, and faced with celluloid, the white surface of which brings out the graduations much more distinctly than lines engraved on a boxwood surface. The celluloid facings should not be polished, as a dull surface is much less fatiguing to the eyes. The most generally used, and on the whole the most convenient size of rule, is about 10½in. long, 1¼in. wide, and about ■in. thick; but 5 in., 8 in., 15 in., 20 in., 24 in. and 40 in. rules are also made. In the centre of the stock of the rule a movable slip is fitted, which constitutes the slide, and corresponds to the lower of the two rules of our rudimentary examples.

[Illustration: FIG. 5.]

From Fig. 5, which is a representation of the face of a Gravêt or Mannheim slide rule, it will be seen that four series of logarithmic graduations or scale-lines are employed, the upper and lower being engraved on the stock or body of the rule, while the other two are engraved upon the slide. The two upper sets of graduations are exactly alike in every particular, and the lower sets are also similar. It is usual to identify the two upper scale-lines by the letters A and B, and the two lower by the letters C and D, as indicated in the figure at the left-hand extremities of the scales.

Referring to the scales C and D, these will each be seen to be a development of the elementary scales of Fig. 3, but in this case each principal space is subdivided, more or less minutely. The principle, however, is exactly the same, so that by moving the slide (carrying scale C), multiplication and division can be mechanically performed in the manner described.

The upper scale-line A consists of two exactly similar scales, placed end to end, the first lying between IL and IC, and the second between IC and IR. The first of these scales will be designated the _left-hand A scale_, and the second the _right-hand A scale_. Similarly the coinciding scales on the slide are the _left-hand B scale_ and the _right-hand B scale_. Each of these four scales is divided (as finely as convenient) as in the case of the C and D scales, but, of course, they are exactly one half the length of the latter.

The two end graduations of both the C and D scales are known as the _left-_ and _right-hand indices_ of these scales. Sometimes they are figured 1 and 10 respectively; sometimes both are marked 1. Similarly IL and IR are the left- and right-hand indices of the A and B lines, while IC is the centre index of these scales. Other division lines usually found on the face of the rule are one on the left-hand A and B scales, indicating the ratio of the circumference of a circle to its diameter, $\pi = 3{\cdot}1416$; and a line on the right-hand B scale marking the position of $(\pi)/(4) = 0{\cdot}7854$, used in calculating the areas of circles. Reference will be made hereafter to the scales on the under-side of the slide, and we need now only add that one of the edges of the rule, usually bevelled, is generally graduated in millimetres, while the other edge has engraved on it a scale of inches divided into eighths or tenths. On the bottom face inside the groove of the rule either one or the other of these scales is continued in such a manner that by drawing the slide out to the right and using the scale inside the rule, in conjunction with the corresponding scale on the edge, it is possible to measure 20 inches in the one case, or nearly 500 millimetres in the other. On the back of the rule there is usually a collection of data, for which the slips given at the end of this work may often be substituted with advantage.

THE NOTATION OF THE SLIDE RULE.

Hitherto our attention has been confined to a consideration of the primary divisions of the scales. The same principle of graduation is, however, used throughout; and after what has been said, this part of the subject need not be further enlarged upon. Some explanation of the method of reading the scales is necessary, as facility in using the instrument depends in a very great measure upon the dexterity of the operator in assigning the correct value to each division on the rule. By reference to Fig. 5, it will be seen that each of the primary spacings in the several scales is invariably subdivided into ten; but since the lengths of the successive primary divisions rapidly diminish, it is impossible to subdivide each main space into the same number of parts that the space 1–2 can be subdivided. This variable spacing of the scales is at first confusing to the student, but with a little practice the difficulty is soon overcome.

With the C or D scale, it will be noticed that the length of the interval 1–2 is sufficient to allow each of the 10 subdivisions to be again divided into 10 parts, so that the whole interval 1–2 is divided into 100. The shorter main space 2–3, and the still shorter one 3–4, only allow of the 10 subdivisions of each being divided into five parts. Each of these main spaces is therefore divided into 50 parts. For the remainder of the scale each of the 10 subdivisions of each main space is divided into two parts only; so that from the main division 4 to the end of the scale the primary spaces are divided into 20 parts only.

In the upper scales A or B, it will be found that—as the space 1–2 is of only half the length of the corresponding space on C or D—the 10 subdivisions of this interval are divided into five parts only. Similarly each of the 10 subdivisions of the intervals 2–3, 3–4, and 4–5 are further divided into two parts only, while for the remainder of the scale only the 10 subdivisions are possible, owing to the rapidly diminishing lengths of the primary spacings.

The values actually given on the rule run from 1 to 10 on the lower scales and from 1 to 100 on the upper scales, and, as explained on page 9, all factors are brought within these ranges of values by multiplying or dividing them by powers of 10. By following this plan, we virtually regard each factor as merely a series of significant figures, and make the necessary modification due to the “powers of 10” when fixing the position of the decimal point in the answer.

Many, however, find it convenient in practice to regard the values on the rule as multiplied or divided by such powers of 10 as may be necessary to suit the factors entering into the calculation. If this plan is adopted, the values given to each graduation of the scales will depend on that given to the left index figure (1) of the lower scales, this being any multiple or submultiple of 10. Thus IL on the D scale may be regarded as 1, 10, 100, 1000, etc., or as 0·1, 0·01, 0·001, 0·0001, etc.; but once the initial value is assigned to the index, the ratio of value must be maintained throughout the whole scale. For example, if 1 on C is taken to represent 10, the main divisions 2, 3, 4, etc., will be read as 20, 30, 40, etc. On the other hand, if the fourth main division is read as 0·004, then the left index figure of the scale will be read as 0·001. The figured subdivisions of the main space 1–2 are to be read as 11, 12, 13, 14, 15, 16, 17, 18 and 19—if the index represents 10,—and as corresponding multiples for any other value of the index.

Independently considered, these remarks apply equally to the A or B scale, but in this case the notation is continued through the second half of the scale, the figures of which are to be read as tenfold values of the corresponding figures in the first half of the scale.

The reading of the intermediate divisions will, of course, be determined by the values assigned to the main divisions. Thus, if IL on D is read as 1, then each of the smallest subdivisions of the space 1–2 will be read as 0·01, and each of the smallest subdivisions of the spaces 2–3 or 3–4 as 0·02, while for the remainder of the scale the smallest subdivisions are read as 0·05. In the A or B scale the subdivisions of the space 1–2 of the first half of the scale are (if IL = 1) read as 0·02, 0·04, etc.; for the divisions 2–3, 3–4, and 4–5, the smallest intervals are read as 0·05 of the primary spaces, and from 5 to the centre index of the scale the divisions represent 0·1 of each main interval. Passing the centre index, which is, now read as 10, the smallest subdivisions immediately following are read 10·2, 10·4, etc., until 20·0 is reached; then we read 20·5, 21·0, 21·5 22·0, etc., until the figured main division 5 is reached. The remainder of the scale is read 51, 52, 53, etc., up to 100, the right-hand index.

Further subdivision of any of the spaces of the rule can be effected by the eye, and after a little practice the operator will become quite expert in estimating any intermediate value. It affords good practice to set 1 on C to 1·04, 1·09, etc. on D, and to read the values on D, under 4, 6, 8, etc. on C. As the exact results are easily calculated mentally, the student, by this means, will receive better instruction in estimating intermediate results than can be given by any diagram.

Some rules will be found figured as shown in Fig. 5; in others, the right-hand upper scales are marked 10, 20, 30, etc. Again, others are marked decimally, the lower scales and the left-hand upper scales being figured 1, 1·1, 1·2, 1·3 ... 2·5, etc. The latter form has advantages from the point of view of the beginner.

The method of reading the A and B scales, just given, applies only when these scales are regarded as altogether independent of the lower pair of scales C and D. Some operators prefer to use the A and B scales, and some the C and D scales, for the ordinary operations of proportion, multiplication, and division. Each method has its advantages, as will be shown, but in the more complex calculations, as involution and evolution, etc., the relation of the upper scales to the lower scales becomes a very important factor.

The distance 1–10 on the upper scales is one-half of the distance 1–10 on the lower scales. Hence any distance from 1, taken on the upper scales, represents _twice the logarithm_ which the same distance represents on the lower scales. In other words, the length which represents log. N on D, would represent 2 log. N on A; and, conversely, the length which represents log. N on A, would represent (log. N)/(2) on D.

Now we have seen (page 8) that multiplying the log. of a number by 2 gives the log. of the square of the number. Hence, above any number on D we find its _square_ on A, or, conversely, below any number on A, we find its _square root_ on D. Thus, above 2 we find 4; under 49, we find 7 and so on. Obviously the same relation exists between the B and C scales.

THE CURSOR OR RUNNER.

All modern slide rules are now fitted with a _cursor_ or _runner_, which usually consists of a light metal frame moving under spring control in grooves in the edges of the stock of the rule. This frame carries a piece of glass, mica or transparent celluloid, about 1 in. square, across the centre of which a fine reference line is drawn exactly at right angles to the line of scales. To “set the cursor” to any value on the scales of the rule, the frame is taken between the thumb and forefinger and adjusted in position until the line falls exactly upon the graduation, or upon an estimated value, between a pair of graduations, as the case may be. Having fixed one number in this way, another value on either of the scales on the slide may be similarly adjusted in reference to the cursor line. The cursor will be found very convenient in making such settings, especially when either or both of the numbers are located by eye estimation. It also finds a very important use in referring the readings of the upper scale to those of the lower, or _vice versa_, while as an aid in continued multiplication and division and complex calculations generally, its value is inestimable.

Multiple Line Cursors.—Cursors can be obtained with _two_ lines, the distance between them being that between 7·854 and 10 on the A scale. The use of this cursor is explained on page 57. Another multiple line cursor has short lines engraved on it, corresponding to the main graduations from 95 to 105 on the respective scales. This is useful for adding or deducting small percentages.

The Broken Line Cursor.—To facilitate setting, broken line cursors are made, in which the hair-line is not continued across the scales, but has two gaps, as shown in Fig. 6.

The Pointed Cursor has an index or pointer, extending over the bevelled edge of the rule, on which is a scale of inches. It is useful for summing the lengths of the ordinates of indicator diagrams, and also for plotting lengths representing the logarithms of numbers, sometimes required in graphic calculations.

The Goulding Cursor.—It has been pointed out that in order to obtain the third or fourth figure of a reading on the 10 in. slide rule, it is frequently necessary to depend upon the operator’s ability to mentally subdivide the space within which the reading falls. This subdivision can be mechanically effected by the aid of the Goulding Cursor (Fig. 7), which consists of a frame fitting into the usual grooves in the rule, and carrying a metal plate faced with celluloid, upon which is engraved a triangular scale A B C. The portion carrying the chisel edges E is not fixed to the cursor proper, but slides on the latter, so that the index marks on the projecting prongs can be moved slightly along the scales of the rule, this movement being effected by the short end of the bent lever F working in the slot as shown. D is a pointer which can be moved along F under spring control. As illustrating the method of use, we will assume that 1 on C is placed to 155 on D, and that we require to read the value on D under 27 on C. This is seen to lie between 4150 and 4200, so setting the pointer D to the line B C—always the first operation—we move the whole along the rule until the index line on the lower prong agrees with 4200. We then move F across the scale until the index line agrees with 4100, set the pointer D to the line A C, and move the lever back until the index line agrees with 27 on the slide. It will then be found that the pointer D gives 85 on A B as the value of the supplementary figures, and hence the complete reading is 4185.

[Illustration: FIG. 6.]

[Illustration: FIG. 8.]

[Illustration: FIG. 7.]

[Illustration: FIG. 9.]

Magnifying Cursors are of assistance in reading the scales, and in a good and direct light are very helpful. In one form an ordinary lens is carried by two light arms hinged to the upper and lower edges of the cursor, so that it can be folded down to the face of the rule when not in use. A more compact form, shown in Fig. 8, consists of a strip of plano-convex glass, on the under-side of which is the hair-line. In a cursor made by Nestler of Lahr, the plano-convex strip is fixed on the ordinary cursor. The magnifying power is about 2, so that a 5 in. rule, having the same number of graduations as a 10 in. rule, can be read with equal facility, by the aid of this cursor.

The Digit-registering Cursor, supplied by Mr. A. W. Faber, London, and shown in Fig. 9, has a semicircular scale running from 0 at the centre upward to –6 and downward to +6. A small finger enables the operator to register the number of digits to be added or subtracted at the end of a lengthy operation, as explained at page 28.

MULTIPLICATION.

In the preliminary notes it was shown that by mechanically adding two lengths representing the logarithms of two numbers, we can obtain the _product_ of these numbers; while by subtracting one log. length from another, the number represented by the latter is divided by the number represented by the former. Hence, using the C and D scales, we have the

RULE FOR MULTIPLICATION.—_Set the index of the C scale to one of the factors on D, and under the other factor on C, find the product on D._

[Illustration: FIG. 10.]

Thus, to find the product of 2 × 4, the slide is moved to the right until the left index (1) of C is brought over 2 on D, when under the other factor (4) on C, is found the required product (8) on D. Following along the slide, to the right, we find that beyond 5 on C (giving 10 on D), we have no scale below the projecting slide (Fig. 10). If we imagine the D scale prolonged to the right, we should have a repetition of the earlier portion, but, as with the two parts of the A scales, the repeated portion would be of tenfold value, and 10 on C would agree with 20 on the prolonged D scale. We turn this fact to account by moving the slide to the left until 10 on C agrees with 2 on D, and we can then read off such results as 2 × 6 = 12; 2 × 8 = 16, etc., remembering that as the scale is now of tenfold value, there will be two figures in the result. Hence, for those who prefer rules, we have the

RULE FOR THE NUMBER OF DIGITS IN A PRODUCT.—_If the product is read with the slide projecting to the_ LEFT, ADD THE NUMBER OF THE DIGITS IN THE TWO FACTORS; _if read with the slide to the_ RIGHT, _deduct 1 from this sum_.

EX.—25 × 70 = 1750.

The product is found with the slide projecting to the _left_, so the number of digits in the product = 2 + 2 = 4.

EX.—3·6 × 25 = 90.

The slide projects to the _right_, and the number of digits in the product is therefore 1 + 2 – 1 = 2.

EX.—0·025 × 0·7 = 0·0175.

The product is obtained with the slide projecting to the _left_, and the number of digits is therefore –1 + 0 = –1.

EX.—0·000184 × 0·005 = 0·00000092.

The sum of the number of digits in the two factors = –3 + (–2) = –5, but as the slide projects to the _right_, the number of digits will be –5 – 1 = –6.

From the last two examples it will be seen that when the first significant figure of a decimal factor does not immediately follow the decimal point, the minus sign is to be prefixed to the number of digits, counting as many digits _minus_ as there are 0's following the decimal point. Thus, 0·03 has –1 digit, 0·0035 has –2 digits, and so on. Some little care is necessary to ensure these minus values being correctly taken into account in determining the number of digits in the answer. For this reason many prefer to treat

decimal factors as whole numbers, and to locate the decimal point according to the usual rules for the multiplication of decimals. Thus, in the last example we take 184 × 5 = 920, but as by the usual rule the product must contain 6 + 3 = 9 decimal places, we prefix six cyphers, obtaining 0·00000092. When both factors consist of integers as well as decimals, the number of digits in the product, and therefore the position of the decimal point, will be determined by the usual rule for whole numbers.

Another method of determining the number of digits in a product deserves mention, which, not being dependent upon the position of the slide, is applicable to all calculating instruments.

GENERAL RULE FOR NUMBER OF DIGITS IN A PRODUCT.—_When the first significant figure in the product is smaller than in_ EITHER _of the factors, the number of digits in the product is equal to the_ SUM _of the digits in the two factors. When the contrary is the case, the number of digits is 1_ LESS _than the sum of the digits in the two factors. When the first figures are the same, those following must be compared._

Estimation of the Figures in a Product.—We have given rules for those who prefer to decide the number of figures by this means, but experience will show that to make the best use of the instrument, the result, as read on the rule, should be regarded merely as the _significant figures of the answer_, the position of the decimal point, if not obvious, being decided by a very rough mental calculation. In very many instances, the magnitude of the result will be evident from the conditions of the problem—_e.g._, whether the answer should be 0·3 in., 3 in., or 30 in.; or 10 tons, 0·1 ton, 100 tons, etc. In those cases where the magnitude of the answer cannot be estimated, and the factors contain many figures, or have a number of 0's following the decimal point, the use of notation by powers of 10 (page 8) is of considerable assistance; but more usually it will be found, that a very rough calculation will settle the point with comparatively little trouble. Considerable practice is needed to work rapidly and with certainty, when using rules. Moreover, the experience thus acquired is confined to slide-rule work. The same time spent in practising the "rough approximation" method will enable reliable results to be obtained rapidly, with the advantage that the method is applicable to calculations generally. However, the choice of methods is a matter of personal preference. Both methods will be given, but whichever plan is followed, the student is strongly advised to cultivate the habit of forming an idea of the magnitude of the result.

EX.—33·6 × 236 = 7930.

Setting 1 on C to 33·6 on D, we read under 236 on D and find 793 on D, as the significant figures of the answer. A rough calculation, as 30 × 200 = 6000, indicates that the result will consist of 4 figures, and is therefore to be read as 7930.

EX.—17,300 × 3780 = 65,400,000.

By factorising with powers of 10

1·73 × 10^4 × 3·78 × 10^3 = 1·73 × 3·78 × 10^7.

Setting 1 on C to 1·73 on D, we read, under 3·78 on C, the result of the simple multiplication, as 6·54. Multiplying by 10^7 moves the decimal point 7 places to the right, and the answer is 65,400,000.

If it is required to find a series of products of which one of the factors is _constant_, set 1 on C to the constant factor on D and read the several products on D, under the respective variable factors.

If the factors are required which will give a constant _product_ (really a case of division), set the cursor to the constant product on D. Then obviously, as the slide is moved along, any pair of factors found simultaneously under the cursor line on C, and on D under index of C, will give the product. A better method of working will be explained when we deal with the inversion of the slide.

It is sometimes useful to remember that although we usually set the slide to the rule, we can obtain the result equally well by setting the rule to the slide. Thus, bringing 1 (or 10) on D to 2 on C, we find on C, _over_ any other factor, _n_ on D, the product of 2 × _n_. But note that the slide and rule have now changed places, and if we use rules for the number of digits in the result, we must now deduct 1 from the sum of the digits in the factors, when the _rule projects_ to the _right of the slide_.

With the ordinary 10 in. rule it will be found in general that the extent to which the C and D scales are subdivided is such as to enable not more than three figures in either factor being dealt with. For the same reason it is impossible to directly read more than the first three figures of any product, although it is often possible—by mentally dividing the smallest space involved in the reading—to correctly determine the fourth figure of a product. Necessarily this method is only reliable when used in the earlier parts of the C and D scales. However, the last numeral of a three-figure, and in some cases the last of a four-figure, product can be

readily ascertained by an inspection of the factors.

EX.—19 × 27 = 513. Placing the L.H. index of C to 19 on D, we find opposite 27 on C, the product, which lies between 510 and 515. A glance at the factors, however, is sufficient to decide that the third figure must be 3, since the product of 9 and 7 is 63, and the last figure of this product must be the last figure in the answer.

EX.—79 × 91 = 7189.

In this case the division line 91 on C indicates on D that the answer lies between 7180 and 7190. As the last figure must be 9, it is at once inferred that the last two figures are 89.

When there are more than three figures in either or both of the factors, the fourth and following figures to the right must be neglected. It is well to note, however, that if the first neglected figure is 5, or greater than 5, it will generally be advisable to increase by 1 the third figure of the factor employed. Generally it will suffice to make this increase in one of the two factors only, but it is obvious that in some cases greater accuracy will be obtained by increasing both factors in this way.

CONTINUED MULTIPLICATION.—To find the product of more than two factors, we make use of the cursor to mark the position of successive products (the value of which does not concern us) as the several factors are taken into the calculation. Setting the index of C to the 1st factor on D, we bring the line of the cursor to the 2nd factor on C, then the index of C to the cursor, the cursor to the 3rd factor, index of C to cursor, and so on, reading the final product on D under the last factor on C. (Note that the 1st factor and the result are read on D; all intermediate readings are taken on C.)

If the rule for the number of digits in a product is used, it is necessary to note the number of times multiplication is effected with the slide projecting to the right. This number, deducted from the sum of the digits of the several factors, gives the number of digits in the product. Ingenious devices have been adopted to record the number of times the slide projects to the right, but some of these are very inconvenient. The author's method is to record each time the slide so projects, by a minus mark, thus –. These can be noted down in any convenient manner, and the sum of the marks so obtained deducted from the sum of the digits in the several factors, gives the number of digits in the product as before explained.

EX.—42 × 71 × 1·5 × 0·32 × 121 = 173,200.

The product given, which is that read on the rule, is obtained as follows:—Set R.H. index of C to 42 on D, and bring the cursor to 71 on C. Next bring the L.H. index of C to the cursor, and the latter to 1·5 on C. This multiplication is effected with the slide to the right, and a memorandum of this fact is kept by making a mark –. Bring the R.H. index of C to the cursor and the latter to 0·32 on C. Then set the L.H. index of C to the cursor and read the result, 1732, on D under 121 on C, while as a slide again projects to the right, a second – memo-mark is recorded. There are 2 + 2 + 1 + 0 + 3 = 8 digits in the factors, and as there were 2 – marks recorded during the operation, there will be 8 – 2 = 6 digits in the product, which will therefore read 173,200 (173,194·56).

For a very rough evaluation of the result, we note that 1·5 × 0·3 is about 0·5; hence, as a clue to the number of figures we have

40 × 70 × 60 = 3000 × 60 = 180,000.

DIVISION.

The instructions for multiplication having been given in some detail, a full discussion of the inverse process of division will be unnecessary.

RULE FOR DIVISION.—_Place the divisor on C, opposite the dividend on D, and read the quotient on D under the index of C._

EX.—225 ÷ 18 = 12·5.

Bringing 18 on C to 225 on D, we find 12·5 under the L.H. index of C.

As in multiplication, the factors are treated as whole numbers, and the position of the decimal point afterwards decided according to the following rule, which, as will be seen, is the reverse of that for multiplication:—

RULE FOR THE NUMBER OF DIGITS IN A QUOTIENT.—_If the quotient is read with the slide projecting to the_ LEFT, _subtract the number of digits in the divisor from those in the dividend; but if read with the slide to the_ RIGHT, ADD _1 to this difference_.[2]

In the above example the quotient is read off with the slide to the right, so the number of digits in the answer = 3 – 2 + 1 = 2.

EX.—0·000221 ÷ 0·017 = 0·013.

Here the number of digits in the dividend is –3, and in the divisor –1. The difference is –2; but as the result is obtained with the slide to the right, this result must be increased by 1, so that the number of digits in the quotient is –2 + 1 = –1, giving the answer as 0·013.

If preferred, the result can be obtained in the manner referred to when considering the multiplication of decimals. Thus, treating the above as whole numbers, we find that the result of dividing 221 by 17 = 13, since the difference in the number of digits in the factors, which is 1, is, owing to the position of the slide, increased by 1, giving 2 as the number of digits in the answer. Then by the rules for the division of decimals we know that the number of decimal places in the quotient is equal to 6 – 3 = 3, showing that a cypher is to be prefixed to the result read on the rule.

As in multiplication, so in division, we have a

GENERAL RULE FOR NUMBER OF DIGITS IN A QUOTIENT.—_When the first significant figure in the_ DIVISOR _is greater than that in the_ DIVIDEND_, the number of digits in the quotient is found by subtracting the digits in the divisor from those in the dividend. When the contrary is the case, 1_ IS TO BE ADDED _to this difference. When the first figures are the same, those following must be compared._

ESTIMATION OF THE FIGURES IN A QUOTIENT.—The method of roughly estimating the number of figures in a quotient needs little explanation.

EX.—3·95 ÷ 5340 = 0·00074.

Setting 534 on C to 3·95 on D we read under the (R.H.) index of C, the significant figures on D, which are 74. Then 3·9 ÷ 5 is about 0·8 and 0·8 ÷ 1000 gives 0·0008 as a rough estimate.

EX.—0·00000285 ÷ 0·000197 = 0·01446.

Regarding this as 2·85 × 10^{–6} ÷ 1·97 × 10^{–4} we divide 2·85 by 1·97 and obtain 1·446. Dividing the powers of 10 we have 10^{–6} ÷ 10^{–4} = 10^{–2}, so the decimal point is to be moved two places to the left and the answer is read as 0·01446.

Another method of dividing deserves mention as of special service when dividing a number of quantities by a _constant divisor_:—Set the index of C to the divisor on D and over any dividend on D, read the quotient on C.

For the division of a _constant dividend_ by a variable divisor, set the cursor to the dividend on D and bring the divisor on C successively to the cursor, reading the corresponding quotients on D under the index of C. Another method which avoids moving the slide is explained in the section on “Multiplication and Division with the Slide Inverted.”

CONTINUED DIVISION, if we can so call such an expression as

(3·14)/(785 × 0·00021 × 4·3 × 64·4) = 0·0688,

may be worked by repeating as follows:—Set 7·85 on C to 3·14 on D, bring cursor to index of C, 2·1 on C to cursor, cursor to index, 4·3 to cursor, cursor to index, 6·44 to cursor, and under index of C read 688 on D as the significant figures of the answer.

For the number of figures in the result, we deduct the sum of the number of digits in the several factors and add 1 for each time the slide projects to the right, which in this case occurs once. There are 3 + (–3) + 1 + 2 = 3 denominator digits, 1 numerator digit, and 1 is to be added to the difference. Therefore there are 1 – 3 + 1 = –1 digits in the answer, which is therefore 0·0688. The foregoing method of working may confuse the beginner, who is apt to fall into the process of continued multiplication. For this reason, until familiarity with combined methods has been acquired, the product of the several denominators should be first found by the continued multiplication process, and the figures in this product determined. Then divide the numerator by this product to obtain the result.

As the denominator product will be read on D, we may avoid resetting the slide by bringing the numerator on C to this product and reading the result on C _over_ the index of D. The slide and rule have here changed places; hence if rules are followed for the

number of figures in the result, 1 must be added to the difference of digits, when the _rule projects_ to the _right of the slide_.

The author's method of recording the number of times division is performed with the slide to the right is by vertical memorandum marks, thus |. The full significance of these memo-marks will appear in the following section.

For a rough calculation to fix the decimal point, in this example we move the decimal points in the factors, obtaining

(3)/(0·8 × 2 × 4 × 6) = (3)/(40) = 0·075.

THE USE OF THE UPPER SCALES FOR MULTIPLICATION AND DIVISION.

Many prefer to use the upper scales A and B, in preference to C and D. The disadvantage is that as the scales are only one-half the length of C or D, the graduation does not permit of the same degree of accuracy being obtained as when working with the lower scales. But the result can always be read directly from the rule without ever having to change the position of the slide after it has been initially set. Hence, it obviates the uncertainty as to the direction in which the slide is to be moved in making a setting.

When the A and B scales are employed, it is understood that the left-hand pair of scales are to be used in the same manner as C and D, and so far the rules relating to the latter are entirely applicable. But in this case the slide is always moved to the right, so that in multiplication the product is found either upon the left or right scales of A. If it is found on the left A scale, the rule for the number of digits in the product is found as for the C and D scales, and is equal to the _sum of the digits in the two factors, minus 1_; but if found on the right-hand A scale, the number of digits in the product is equal to the sum of the digits in the two factors.

In division, similar modifications are necessary. If when moving the slide to the right the division can be completely effected by using the L.H. scale of A, the quotient (read on A above the L.H. of index B) has a number of digits equal to the number in the dividend, less the number in the divisor, _plus 1_. But if the division necessitates the use of both the A scales, the number of digits in the quotient equals the number in the dividend, less the number in the divisor.

RECIPROCALS.

A special case of division to be considered is the determination of the _reciprocal_ of a number _n_, or (1)/(_n_). Following the ordinary rule for division, it is evident that setting _n_ on C to 1 on D, gives (1)/(_n_) on D under 1 on C. It is more important to observe that by inverting the operation—setting 1 (or 10) on C to _n_ on D—we can read (1)/(_n_) on C over 1 (or 10) on D. Hence whenever a result is read on D under an index of C, we can also read its reciprocal on C over whichever index of D is available.

The Number of Digits in a Reciprocal is obvious when _n_ = 10, 100, or any power (_p_) of 10. Thus (1)/(10) = 0·1; (1)/(100) = 0·01; (1)/(10^{_p_}) = 1 preceded by _p_ – 1 cyphers. For all other cases we have the rule:—_Subtract from 1 the number of digits in the number._

EX.—(1)/(339) = 0·00295.

There are 3 digits in the number; hence, there are 1 – 3 = –2 digits in the answer.

EX.—(1)/(0·0000156) = 64,100.

There are –4 digits in the number; hence, there are 1 – (–4) = 5 digits in the result.

CONTINUED MULTIPLICATION AND DIVISION.

By combining the rules for multiplication and division, we can readily evaluate expressions of the form (_a_)/(_b_) × (_c_)/(_d_) × (_e_)/(_f_) × (_g_)/(_h_) = _x_. The simplest case, (_a_ × _c_)/(_b_) can be solved by one setting of the slide.[3] Take as an example, (14·45 × 60)/(8·5) = 102. Setting 8·5 on C to 14·45 on D, we can, if desired, read 1·7 on D under 1 on C, as the quotient. However, we are not concerned with this, but require its multiplication by 60, and the slide being already set for this operation, we at once read under 60 on C the result, 102, on D. The figures in the answer are obvious.

When there are more factors to take into account, we place the cursor over 102 on D, bring the next divisor on C to the cursor, move the cursor to the next multiplier on C, bring the next divisor on C to the cursor, and so on, until all the factors have been dealt with. Note that only the first factor and the result are read on D; also _that the cursor is moved for multiplying and the slide for

dividing_.

Number of Digits in Result in Combined Multiplication and Division.—For those who use rules the author's method of determining the decimal point in combined multiplication and division may be used. Each time _multiplication_ is performed with the slide projecting to the _right_, make a – mark; each time _division_ is effected with the slide to the right, make a | mark; _but allow the_ | _marks to cancel the_ – _marks as far as they will_. Subtract the sum of the digits in the denominator from the sum of digits in the numerator, and to this difference _add_ any uncancelled memo-marks, if of | character, or _subtract_ them if of – character.

EX.—(43·5 × 29·4 × 51 × 32)/(27 × 3·83 × 10·5 × 1·31) = 1468.

[Sidenote: ■ ■ ■ ■]

Set 27 on C to 43·5 on D, and as with this _division_ the slide is to the right, make the first ■ mark. Bring cursor to 29·4 on C, and as in this _multiplication_ the slide is to the right, make the first – mark, cancelling as shown. Setting 3·83 on C to the cursor, requires the second ■ mark, which, however, is cancelled in turn by the multiplication by 51. The division by 10·5 requires the third ■ mark, and after multiplying by 32 (requiring no mark) the final division by 1·31 requires the fourth ■ mark. Then, as there are 8 numerator digits, 6 denominator, and 2 uncancelled memo-marks (which, being 1, are additive) we have

Number of digits in result = 8 – 6 + 2 = 4.

Had the uncancelled marks been – in character, the number of digits would have been 8 – 6 – 2 = 0.

For quantities less than 0·1 the digit place numbers will be _negative_. The troublesome addition of these may be avoided by transferring them to the opposite side and treating them as positive.

_2_ _4_ 0·00356 × 27·1 × 0·08375 Thus:— ■■■■■■■■■■■■■■■■■■■■■■■■■■■■ = 288 0·1426 × 9·85 × 0·00002 _2_ _1_ _1_

The first numerator, 0·00356, has –2 digits. Note this by placing 2 _below the lower line_ as shown. 27·1 has 2 digits; place 2 over it. 0·08375 has –1 digit; hence place 1 _below the lower line_. The first denominator has no digits; the second, 9·85, has 1 digit; hence place 1 under it. 0·00002 has –4 digits; place 4 _above the upper line_. The sum of the top series is 2 + 4 = 6; of the bottom series 2 + 1 + 1 = 4. Subtracting the bottom from the top, we have 6 – 4 = 2 digits, to which 1 has to be added for an uncancelled memo-mark, and the result is read as 288.

Moving the decimal point often facilitates matters. Thus, (32·4 × 0·98 × 432 × 0·0217)/(4·71 × 0·175 × 0·00000621 × 412000) is much more conveniently dealt with when re-arranged as (32·4 × 9·8 × 432 × 2·17)/(4·71 × 17·5 × 6·21 × 4·12) = 141.

To determine the number of figures in the result by rough cancelling and mental calculation, we note that 4·71 enters 432 about 100 times; 9·8 enters 17·5 about 2; 6·21 into 32·4 about 5; and 2·17 into 4·12 about 2. This gives (500)/(4) = 125, showing that the result contains 3 digits. From the slide rule we read 141, which is therefore the result sought.

The occasional traversing of the slide through the rule, to interchange the indices—a contingency which the use of the C and D scales always involves—may often be avoided by a very simple expedient. Such an example as (6·19 × 31·2 × 422)/(1120 × 8·86 × 2.09) = 3·93 is sometimes cited as a particularly difficult case. Working through the expression as given, two traversings of the slide are necessary; but by taking the factors in the slightly different order, (6·19 × 31·2 × 422)/(8·86 × 2·09 × 1120), _so that the significant figures of each pair are more nearly alike_, we not only avoid any traversing the slide, but we also reduce the extent to which the slide is moved to effect the several divisions.

Such cases as (_a_ × _b_)/(_c_ × _d_ × _e_ × _f_ × _g_) or (_a_ × _b_ × _c_ × _d_ × _e_)/(_f_ × _g_) really resolve themselves into (_a_ × _b_ × 1 × 1 × 1)/(_c_ × _d_ × _e_ × _f_ × _g_) and (_a_ × _b_ × _c_ × _d_ × _e_)/(_f_ × _g_ × 1 × 1 × 1), but, of course, if rules are used to locate the decimal point, the 1's so (mentally) introduced are not to be counted as additional figures in the factors.

MULTIPLICATION AND DIVISION WITH THE SLIDE INVERTED.

If the slide be inverted in the rule but with the same face uppermost, so that the ■ scale lies adjacent to the A scale, and the right and left indices of the slide and rule are placed in coincidence, we find the product of any number on D by the coincident number on

■ (readily referred to each other by the cursor) is always 10. Hence, by reading the numbers on ■ as decimals, we have over any unit number on D, its _reciprocal_ on ■. Thus 2 on D is found opposite 0·5 on ■; 3 on D opposite to 0·333; while opposite 8 on ■ is 0·125 on D, etc. The reason of this is that the sum of the lengths of the slide and rule corresponding to the factors, is always equal to the length corresponding to the product—in this case, 10.

It will be seen that if we attempt to apply the ordinary rule for multiplication, with the slide inverted, we shall actually be multiplying the one factor taken on D by the _reciprocal_ of the other taken on ■. But multiplying by the _reciprocal of a number_ is equivalent to _dividing_ by that number, and _dividing_ a factor by the _reciprocal_ of a number is equivalent to _multiplying_ by that number. It follows that with the slide inverted the operations of multiplication and division are reversed, as are also the rules for the number of digits in the product and the position of the decimal point. Hence, in multiplying with the slide inverted, we place (by the aid of the cursor) one factor on ■ opposite the other factor on D, and read the result on D under either index of ■. It follows that with the slide thus set, any pair of coinciding factors on ■ and D will give the same constant product found on D under the index of ■. One useful application of this fact is found in selecting the scantlings of rectangular sections of given areas or in deciding upon the dimensions of rectangular sheets, plates, cisterns, etc. Thus by placing the index of ■ to 72 on D, it is readily seen that a plate having an area of 72 sq. ft. may have sides 8 by 9 ft., 6 by 12, 5 by 14·4, 4 by 18, 3 by 24, 2 by 36, with innumerable intermediate values. Many other useful applications of a similar character will suggest themselves.

PROPORTION.

With the slide in the ordinary position and with the indices of the C and D scales in exact agreement, the _ratio_ of the corresponding divisions of these scales is 1. If the slide is moved so that 1 on C agrees with 2 on D, we know that under any number _n_ on C is _n_ × 2 on D, so that if we read numerators on C and denominators on D we have

C 1 1·5 2 3 4 ■■■

read off. It must be remembered that if the slide is moved in the direction of notation (to the _right_), the values read thereon have a tenfold _greater_ value; if the slide is moved to the _left_, the readings thereon are _decreased_ in a tenfold degree. Although preferred by many, in the form given, the case is obviously one of multiplication, and is so treated in the Data Slips at the end of the book.

We have seen that the relation which the upper scales bear to the lower set is such that over any number on D is its square on A, and, conversely, under any number on A is its square root on D, the same remarks applying to the C and B scales on the slide. Taking the values engraved on the rule, we have on D, numbers lying between 1 and 10, and on A the corresponding squares extending from 1 to 100. Hence the squares of numbers between 1 and 10, or the roots of numbers between 1 and 100, can be read off on the rule by the aid of the cursor. All other cases are brought within these ranges of values by factorising with powers of 10, as before explained.

The more practical rule is the following:—

To Find the Square of a Number, set the cursor to the number on D and read the required square on A under the cursor. The rule for

The Number of Digits in a Square is easily deducible from the rule for multiplication. If the square is read on the _left_ scale of A, it will contain _twice_ the number of digits in the original number _less_ 1; if it is read on the _right_ scale of A, it will contain _twice_ the number of digits in the original number.

EX.—Find the square of 114.

Placing the cursor to 114 on D, it is seen that the coinciding number on A is 13. As the result is read off on the _left_ scale of A, the number of digits will be $(3 \times 2) - 1 = 5$, and the answer is read as 13,000. The true result is 12,996.

EX.—Find the square of 0·0093.

The cursor being placed to 93 on D, the number on A is found to be 865. The result is read on the _right_ scale of A, so the number of digits = $-2 \times 2 = -4$, and the answer is read as 0·0000865 [0·00008649].

Square Root.—The foregoing rules suggest the method of procedure in the inverse operation of extracting the square root of a given number, which will be found on the D scale opposite the number on the A scale. It is necessary to observe, however, that if the number consists of an _odd_ number of digits, it is to be taken on the _left-hand_ portion of the A scale, and the number of digits in the root = $(N + 1)/(2)$, N being the number of digits in the original number. When there is an even number of digits in the number, it is to be taken on the _right-hand_ portion of the A scale, and the root contains _one-half_ the number of digits in the original number.

EX.—Find the square root of 36,500.

As there is an _odd_ number of digits, placing the cursor to 365 on the L.H. A scale gives 191 on D. By the rule there are $(N + 1)/(2) = (5 + 1)/(2) = 3$ digits in the required root, which is therefore read as 191 [191·05].

EX.—Find $\sqrt{}$(0·0098.)

Placing the cursor to 98 on the right-hand scale of A (since −2 is an _even_ number of digits), it is seen that the coinciding number on D is 99. As the number of digits in the number is −2, the number of digits in the root will be $(-2)/(2) = -1$. It will therefore be read as 0·099 [0·09899+].

EX.—Find $\sqrt{}$(0·098).

The number of digits is −1, so under 98 on the left scale of A, we find 313 on D. By the rule the number in the root will be $(-1 + 1)/(2) = 0$, and the root is therefore read as 0·313 [0·313049+].

EX.—Find $\sqrt{}$(0·149.)

As the number of digits (0) is _even_, the cursor is set to 149 on the right-hand scale of A, giving 386 on D. By the rule, the number of digits in the root will be $(0)/(2) = 0$, and the root will be read as 0·386 [0·38605+].

Another method of extracting the square root, by which more accurate readings may generally be obtained, is by using the C and D scales only, with the slide inverted. If there is an _odd_ number of digits in the number, the _right_ index, or if an even number of digits the _left_ index, of the inverted scale ■ is placed so as to coincide with the number on D of which the root is sought. Then with the cursor, the number is found on D which coincides with the same number on ■, which number is the root sought.

EX.—Find √(22·2.)

Placing the left index of ■ to 222 on D, the two equal coinciding numbers on ■ and D are found to be 4·71.

Note that under the cursor line we have the original number, 22·2, on A, and from this the number of digits in the root is determined as before.

The plan of finding the square of a number by ordinary multiplication is often very convenient. The inverse process of finding a square root by trial division is not to be recommended.

To obtain a close value of a root or to verify one found in the usual way, the author has, on occasion, adopted the following plan:—Set 1 (or 10) on B to the number on the A scale (L.H. or R.H. as the case may require), and bring the cursor to the number on D. If the root found is correct, the readings on C under the cursor and on D under the index of C, will be in exact agreement.

If 1 on B is placed to a number _n_ on the L.H. A scale, the student will note that while root _n_ is read on D under 1 on C, the root of 10 _n_ is read on D under 10 on B. Hence, if preferred, the number can be taken always on the first scale of A and the root read under 1 or 10 on B, according to whether there is an odd or even number of digits in the number. Obviously the second root is the first multiplied by √(10).

CUBES AND CUBE ROOTS.

In raising a number to the third power, a combination of the preceding method and ordinary multiplication is employed.

TO FIND THE CUBE OF A NUMBER.—_Set the_ L.H. _or_ R.H. _index of C to the number on D, and opposite the number_ ON THE LEFT-HAND _scale of B read the cube on the_ L.H. _or_ R.H. _scale of A_.

By this rule four scales are brought into requisition. Of these, the D scale and the L.H. B scale are _always_ employed, and are to be read as of equal denomination. The values assigned to the L.H. and R.H. scales of A will be apparent from the following considerations.

Commencing with the indices of C and D coinciding, and moving the slide to the right, it will be seen that, working in accordance with the above rule, the cubes of numbers from 1 to 2·154 (= ■(10)) will be found on the first or L.H. scale of A. Moving the slide still farther to the right, we obtain _on the_ R.H. _A scale_ cubes of numbers from 2·154 to 4·641 (or ■(10) to ■(100)). Had we a _third_ repetition of the L.H. A scale, the L.H. index of C could be still further traversed to the right, and the cubes of numbers from 4·641 to 10 read off on this prolongation of A. But the same end can be attained by making use of the R.H. index of C, when, traversing the slide to the right as before, the cubes of numbers from 4·641 to 10 on D can be read off _on the_ L.H. _A scale_ over the corresponding numbers on the L.H. B scale. Hence, using the L.H. index of C, the readings on the L.H. A scale may be regarded comparatively as units, those on the R.H. A scale as tens; while for the hundreds we again make use of the L.H. A scale in conjunction with the _right-hand_ index of C.

By keeping these points in view, the number of digits in the cube (N) of a given number (_n_) are readily deduced. Thus, if the units scale is used, N = 3_n_ – 2; if the tens scale, N = 3_n_ – 1; while if the hundreds scale be used, N = 3_n_. Placed in the form of rules:—

N = 3_n_ – 2 when the product is read on the L.H. scale of A with the slide to the _right_ (units scale).

N = 3_n_ – 1 when the product is read on the R.H. scale of A; slide to the _right_ (tens scale).

N = 3_n_ when the product is read on the L.H. scale of A with the slide to the _left_ (hundreds scale).

With decimals the same rule applies, but, as before, the number of digits must be read as –1, –2, etc., when one, two, etc., cyphers follow immediately after the decimal point.

EX.—Find the value of 1·4^3.

Placing the L.H. index of C to 1·4 on D, the reading on A opposite 1·4 on the L.H. scale of B is found to be about 2·745 [2·744].

EX.—Find the value of 26·4^3.

Placing the L.H. index of C to 26·4 on D, the reading on A opposite 26·4 on the L.H. scale of B is found to be about 18,400 [18,399·744].

EX.—Find the value of 7·3^3.

In this case it becomes necessary to use the R.H. index of C, which is set to 7·3 on D, when opposite 7·3 on the L.H. scale of B is read 389 [389·017] on A.

EX.—Find the value of 0·073^3.

From the setting as before it is seen that the number of digits in the number must be multiplied by 3. Hence, as there is –1 digit in 0·073, there will be –3 in the cube, which is therefore read 0·000389.

The last two examples serve to illustrate the principle of factorising with powers of 10. Thus

0·073 = 7·3 × 10^{–2}; 0·073^3 = 7·3^3 × (10^{–2})^3 = 389 × 10^{–6} = 0·000389.

Cube Root (_Direct Method_).—One method of extracting the cube root of a number is by an inversion of the foregoing operation. Using the same scales, _the slide is moved either to the right or left until under the given number on A is found a number on the_ L.H. _B scale, identical with the number simultaneously found on D under the right or left index of C_. This number is the required cube root.

From what has already been said regarding the combined use of these scales in cubing, it will be evident that in extracting the cube root of a number, it is necessary, in order to decide which scales are to be used, to know the number of figures to be dealt with. We therefore (as in the arithmetical method of extraction) point off the given number into sections of three figures each, commencing at the decimal point, and proceeding to the left for numbers greater than unity, and to the right for numbers less than unity. Then if the first section of figures on the left consists of—

1 figure, the number will evidently require to be taken on what we have called the “units” scale—_i.e._, on the L.H. scale of A, using the L.H. index of C.

If of 2 figures, the number will be taken on the “tens” scale—_i.e._, on the R.H. scale of A, using the L.H. index of C.

If of 3 figures, the number will be taken on the “hundreds” scale—_i.e._, on the L.H. scale of A, using the R.H. index of C.

To determine the number of digits in cube roots it is only necessary to note that when the number is pointed off into sections as directed, there will be one figure in the root for every section into which the number is so divided, whether the _first_ section consists of 1, 2, or 3 digits.

Of numbers wholly decimal, the cube roots will be decimal, and for every group of _three_ 0s immediately following the decimal point, _one_ 0 will follow the decimal point in the root. If necessary, 0s must be added so as to make up complete multiples of 3 figures before proceeding to extract the root. Thus 0·8 is to be regarded as 0·800, and 0·00008 as 0·000080 in extracting cube roots.

EX.—Find ■(14,000.)

Pointing the number off in the manner described, it is seen that there are _two_ figures in the first section—viz., 14. Setting the cursor to 14 on the R.H. scale of A, the slide is moved to the right until it is seen that 241 on the L.H. scale of B falls under the cursor, when 241 on D is under the L.H. index of C. Pointing 14,000 off into sections we have 14 000—that is, _two_ sections. Therefore, there are two digits in the root, which in consequence will be read 24·1 [24·1014+].

EX.—Find ■(0·162.)

As the divisional section consists of _three_ figures, we use the “hundreds” scale. Setting the cursor to 0·162 on the L.H. A scale, and using the R.H. index of C, we move the slide to the left until under the cursor 0·545 is found on the L.H. B scale, while the R.H. index of C points to 0·545 on D, which is therefore the cube root of 0·162.

EX.—Find ■(0·0002.)

To make even multiples of 3 figures requires the addition of 00; we have then 200, the cube root of which is found to be about 5·85. Then, since the first divisional group consists of 0s, one 0 will follow the decimal point, giving ■(0·0002) = 0·0585 [0·05848].

Cube Root (Inverted Slide Method).—Another method of extracting the cube root involves the use of the inverted slide. Several methods are used, but the following is to be preferred:—_Set the_ L.H. _or_ R.H. _index of the slide to the number on A, and the number on ■ (i.e., B inverted), which coincides with the same number on D, is the required root._

Setting the slide as directed, and using first the L.H. index of the slide and then the R.H. index, it is always possible to find _three_ pairs of coincident values. To determine which of the three is the required result is best shown by an example.

EX.—Find ■(5,) ■(50,) and ■(500.)

Setting the R.H. index of the slide to 5 on A, it is seen that 1·71 on D coincides with 1·71 on ■. Then setting the L.H. index to 5 on A, further coincidences are found at 3·68 and at 7·93, the three values thus found being the required roots. Note that the first root was found on that portion of the D scale lying under 1 to 5 on A; the second root on that portion lying under 5 to 50 on A; and the third root on that portion of D lying under 50 to 100 on A. In this connection, therefore, scale A may always be considered to be divided into three sections—viz., 1 to _n_, _n_ to 10_n_, and 10_n_ to 100. For all numbers consisting of 1, 1 + 3, 1 + 6, 1 + 9—_i.e._, of 1, 4, 7, 10, or −2, −5, etc., figures—the coincidence under the first section is the one required. If the number has 2, 5, 8, or −1, −4, −7, etc., figures, the coincidence under the second section is correct, while if the number has 3, 6, 9, or 0, −3, etc., figures, the coincidence under the last section is that required. The number of digits in the root is determined by marking off the number into sections, as already explained.

Cube Root (Pickworth's Method).—One of the principal objections to the two methods described is the difficulty of recollecting which scales are to be employed and with which index of the slide they are to be used. With the direct method another objection is that the readings to be compared are often some distance apart, the maximum distance intervening being _two-thirds_ of the length of the rule. To carry the eye from one to another is troublesome and time-taking. With the inverted scale method the reading of a scale reversed in direction and with the figures inverted is also objectionable.

With the author's method these objections are entirely obviated. The _same scales and index are always used_, and are read in their normal position. The three roots of _n_, 10_n_ and 100_n_ (_n_ being less than 10 and not less than 1) are given with one setting and appear in their natural sequence, no traversing of the slide being needed. The readings to be compared are always close together, the maximum distance between them being _one-sixth_ of the length of the rule. The setting is always made in the earlier part of the scales where closer readings can be obtained, and finally, if desired, the result may be readily verified on the lower scales by successive multiplication.

For this method two gauge points are required on C. To conveniently locate these, set 53 on C to 246 on D; join 1 on D to 1 on A with a straight-edge and with a needle point draw a short fine line on C. Set 246 on C to 53 on D, and repeat the process at the other end of the rule. The gauge points thus obtained (dividing C into three equal parts) will be at 2·154 and 4·641, and should be marked ■(10) and ■(100) respectively.[6]

EX.—Find ■(2·86,) ■(28·6) and ■(286).

Set cursor to 2·86 on A and drawing the slide to the right find 1·42 under 1 on C, when 1·42 on B is under the cursor. Then reading under 1, ■(10) and ■(100,) we have

■(2·86) = 1·42; ■(28·6) = 3·06 and ■(286) = 6·59.

It will be seen that factorising with powers of 10, we multiply the initial root by ■(10) and ■(100). Obviously the three roots will always be found on D, in their natural order and at intervals of one-third the length of the rule. The number of digits in the roots of numbers which do not lie between 1 and 1000, is found as before explained.

In any method of extracting cube roots in which the slide has to be adjusted to give equal readings on B and D, the author has found it of advantage to adopt the following plan:—The cursor being set to, say, 4·8 on A, bring a near _main_ division line on B, as 1·7, to the cursor; then 1 on C is at 1·68 on D. The difference in the readings is two small divisions on D, and moving the slide forward by _one-third the space representing this difference_, we obtain 1·687 as the root required. With a little practice it is possible to obtain more accurate results by this method than by comparing the reading on D with that on the less finely-graded B

scale.

MISCELLANEOUS POWERS AND ROOTS.

In addition to squares and cubes, certain other powers and roots may be readily obtained with the slide rule.

Two-thirds Power.—The value of N^■ is found on A over ■■N on D. The number of digits is decided by the rule for squares, working from the number of digits in the cube root. It will often be found preferable to treat N^■ as N ÷ ■■N, as in this way the magnitude of the result is much more readily appreciated.

Three-two Power.—N^{⅔■} can be obtained by cubing the square root, deciding the number of digits in each process. For the reason just given, it is preferable to regard N^{⅔■} as N × √■N.

Fourth Power.—For N^4 set the index of C to N on D and over N on C read N^4 on A; or find the square of the square of N, deciding the number of digits at each step.

Fourth Root.—Similarly for ■■N, take the square root of the square root.

Four-third Power.—N^{■/■} = N^{1·33} (useful in gas-engine diagram calculations) is best treated as N × ■■N.

Other powers can be found by repeated multiplication. Thus setting 1 on B to N on A, we have on A, N^2 over N; N^3 over N^2; N^4 over N^3; N^5 over N^4, etc. In the same way, setting N on B to N on D, we can read such values as N^¾, N^■, etc.

POWERS AND ROOTS BY LOGARITHMS.

For powers or roots other than those of the simple forms already discussed, it is necessary to employ the usual logarithmic process. Thus to find _a^n_ = _x_, we multiply the logarithm of _a_ by _n_, and find the number _x_ corresponding to the logarithm so obtained. Similarly, to find _■√■a_ = _x_ we divide the logarithm of _a_ by _n_, and find the number _x_ corresponding to the resulting logarithm.

The Scale of Logarithms.—Upon the back of the slide of the Gravêt and similar slide rules there will be found three scales. One of these—usually the centre one—is divided equally throughout its entire length, and figured from right to left. It is sometimes marked L, indicating that it is a scale giving logarithms. The whole scale is divided primarily into ten equal parts, and each of these subdivided into 50 equal parts. In the recess or notch in the right-hand end of the rule is a reference mark, to which any of the divisions of this evenly-divided scale can be set.

As this decimally-divided scale is equal in length to the logarithmic scale D, and is figured in the reverse direction, it results that when the slide is drawn to the right so that the L.H. index of C coincides with any number on D, the reading on the equally-divided scale will give the decimal part of the logarithm of the number taken on D. Thus if the L.H. index of C is placed to agree with 2 on D, the reading of the back scale, taken at the reference mark, will be found to be 0·301, the logarithm of 2. It must be distinctly borne in mind that the number so obtained is the _decimal part_ or _mantissa_ of the logarithm of the number, and that to this the characteristic must be prefixed in accordance with the usual rule—viz., _The integral part, or characteristic of a logarithm is equal to the number of digits in the number, minus 1. If the number is wholly decimal, the characteristic is equal to the number of cyphers following the decimal point, plus 1._ In the latter case the characteristic is negative, and is so indicated by having the minus sign written _over_ it.

To obtain any given power or root of a number, the operation is as follows:—Set the L.H. index of C to the given number on D, and turning the rule over, read opposite the mark in the notch at the right-hand end of the rule, the decimal part of the logarithm of the number. Add the characteristic according to the above rule, and multiply by the exponent of the power, or divide by the exponent of the root. Place the _decimal part_ of the resultant reading, taken on the scale of equal parts, opposite the mark in the aperture of the rule, and read the answer on D under the L.H. index of C, pointing off the number of digits in the answer in accordance with the number of the characteristic of the resultant.

EX.—Evaluate 36^{1·414}.

Set 1 on C to 36 on D and read the decimal part of log. 36 on the scale of logarithms on the back of the slide. This value is found to be 0·556. As there are two digits in the number, the characteristic will be 1; hence log. 36 = 1·556. Multiply by 1·414, using the C

and D scales, and obtain 2·2 as the log. of the result. Set the decimal part, 0·2, on the log. scale to the mark in the notch at the end of the rule and read 1585 on D under 1 on C. Since the log. of the result has a characteristic 2, there will be 3 digits in the result, which is therefore read as 158·5.

This example will suffice to show the method of obtaining the nth power or the _n_th root of _any_ number.

OTHER METHODS OF OBTAINING POWERS AND ROOTS.

A simple method of obtaining powers and roots, which may serve on occasion, is by scaling off proportional lengths on the D scale (or the A scale) of the ordinary rule. Thus, to determine the value of 1·25^{1·67} we take the actual length 1–1·25 on D scale, and increase it by any convenient means in the proportion of 1 ■ 1·67. Then with a pair of dividers we set off this new length from 1, and obtain 1·44 as the result. One convenient method of obtaining the desired ratio is by a pair of proportional compasses. Thus to obtain 1·52^{1■/■■}, the compasses would be set in the ratio of 16 to 17, and the smaller end opened out to include 1–1·52 on the D scale; the opening in the large end of the compasses will then be such that setting it off from 1 we obtain 1·56 on D as the result sought.

[Illustration: FIG. 11.]

The converse procedure for obtaining the _n_th root of a number N will obviously resolve itself into obtaining (1)/(_n_)th of the scale length 1-N, and need not be further considered.

Simple geometrical constructions are also used for obtaining scale lengths in the required ratio. A series of parallel lines ruled on transparent celluloid or stout tracing paper may be placed in an inclined position on the face of the rule and adjusted so as to divide the scale as desired. When much work is to be done which requires values to be raised to some constant but comparatively low power, _n_, the author has found the following device of assistance:—On a piece of thin transparent celluloid a line OC is drawn (Fig. 11) and in this a point B is taken such that (OC)/(OB) is the desired ratio. It is convenient to make OB = 1–10 on the A scale, so that assuming we require a series of values of _v_^{1·35}, OB would be 12·5 cm. and OC, 16·875 cm. On these lines semi-circles are drawn as shown, both passing through the point O.

Applying this cursor to the upper scales so that the point O is on 1 and the semi-circle O M B passes through _v_ on A, the larger semi-circle will give on A the value of _v^n_. Thus for _p_ _v^n_ = 39·5 × 4·9^{1·35}, set 1 on B to 39·5 on A (Fig. 12) and apply the cursor to the working edge of B, so that O agrees with 1 and O M B passes through 4·9 on B. The larger semi-circle then cuts the edge of the slide on a point, giving 337 on A as the result required.

Of course any number of semi-circles may be drawn, giving different ratios. If a number of evenly-spaced divisions are used as bases, the device affords a simple means of obtaining a succession of small powers or roots, while it also finds a use in determining a number of geometric means between two values as is required in arranging the speed gears of machine tools, etc. The converse operation of finding roots will be evident as will also many other uses for which the device is of service.

[Illustration: FIG. 12.]

The lines should be drawn in Indian ink with a very sharp pen and on the _under_ side of the celluloid so that the lines lie in close contact with the face of the rule.

The Radial Cursor, another device for the same purpose, is always used in conjunction with the upper scales. As will be seen from Fig. 13, the body of the cursor P carries a graduated bar S which can be removed in a direction transverse to the rule, and adjusted to any desired position. Pivoted to the lower end of S is a radial arm R of transparent celluloid on which a centre line is engraved.

A reference to the illustration will show that the principle involved is that of similar triangles, the width of the slide being used as one of the elements. Thus, to take a simple case, if 2 on S is set to the index on P, and 1 on B is brought to N on A, then by swinging the radial arm until its centre line agrees with 1 on C, we can read N^2 on A. Evidently, since in the two similar triangles A O N^2 and N _t_ N^2 the length of A O is twice that of N _t_, it results that A N^2 = 2 A N. In general, then, to find the _n_th power of a number, we set the cursor to 1 or 10 on A, bring _n_ on the cross bar S to the index on the cursor, and 1 on B to N on A. Then to 1 on C we set the line on the radial arm, and under the latter read N^{_n_} on A. The inverse proceeding for finding the _n_th root will be obvious.

[Illustration: FIG. 13.]

An advantage offered by this and analogous methods of obtaining powers and roots is that the result is obtained on the ordinary scale of the rule, and hence it can be taken directly into any further calculation which may be necessary.

COMBINED OPERATIONS.

Thus far the various operations have been separately considered, and we now pass on to a consideration of the methods of working for solving the various formulæ met with in technical calculations. We propose to explain the methods of dealing with a few of the more generally used expressions, as this will suffice to suggest the procedure in dealing with other and more intricate calculations. In solving the following problems, both the upper and lower scales are used, and the relative value of the several scales must be observed throughout. Thus, in solving such an expression as √((74·5)/(15·8)) = 6·86, the division is first effected by setting 15·8 on B to 745 on A. From the relation of the two parts of the upper scales (page 37) we know that such values as 7·45, 745, etc., will be taken on the _left-hand_ A and B scales, while values as 15·8, 1580, etc., will be taken on the _right-hand_ A and B scales. Hence, 15·8 on the R.H. B scale is set to 745 on the L.H. A scale, and the result read on D under the index of C. Had both values been taken on the L.H. A and B scales, or both on the R.H. A and B scales, the results would have corresponded to _x_ = √((7·45)/(1·58)) = 2·17, or to _x_ =√((74·5)/(15·8)) = 2·17, _i.e_., to (6·86)/(√(10)). Hence if a wrong choice of scales has been made, we can correct the result by multiplying or dividing by √(10) as the case may require. If the result is read on D, set to it the centre index (10) of B and read the corrected result under the index of C.

To solve _a_ × _b_^2 = _x_. Set the index of C to _b_ on D, and over _a_ on B read _x_ on A.

To solve (_a_^2)/(_b_) = _x_. Set _b_ on B to _a_ on D by using the cursor, and over index of B read _x_ on A.

To solve (_b_)/(_a_^2) = _x_. Set _a_ on C to _b_ on A, and over 1 on B read _x_ on A.

To solve (_a_ × _b_^2)/(_c_) = _x_. Set _c_ on B to _b_ on D, and over _a_ on B read _x_ on A.

To solve (_a_ × _b_)^2 = _x_. Set 1 on C to _a_ on D, and over _b_ on C read _x_ on A.

To solve ((_a_)/(_b_))^2 = _x_. Set _b_ on C to _a_ on D, and over 1 on C read _x_ on A.

To solve √(_a_ × _b_) = _x_. Set 1 on B to _a_ on A, and under _b_ on B read _x_ on D.

To solve √((_a_)/(_b_)) = _x_. Set _b_ on B to _a_ on A, and under 1 on C read _x_ on D.

To solve _a_ (_b_)/(_c_^2) = _x_. Set _b_ on C to _c_ on D and over _a_ on B read _x_ on A.

To solve _c_√((_a_)/(_b_)) = _x_. Set _b_ on B to _a_ on A, and under _c_ on C read _x_ on D.

To solve (√_■a_)/(_b_) = _x_. Set _b_ on C to _a_ on A, and under 1 on C read _x_ on D.

To solve (_a_)/(√_■b_) = _x_. Set _b_ on B to _a_ on D, and under 1 on C read _x_ on D.

To solve _b_√_■a_ = _x_. Set 1 on C to _b_ on D, and under _a_ on B read _x_ on D.

To solve √(_a_^3) = _x_. Treat as _a_√_■a_.

To solve _a_√(_b_^3) = _x_. Treat as _a_√_■b_ × _b_.

To solve (√_■a_^3)/(_b_) = _x_. Treat as (√_■a_ × _a_)/(_b_).

To solve √((_a_^3)/(_b_)) = _x_. Treat as (√_■a_ × _a_)/(√_■b_) = √((_a_)/(_b_)) × _a_.

To solve √((_a_ × _b_)/(_c_)) = _x_. Set _c_ on B to _a_ on A, and under _b_ on B read _x_ on D.

To solve (_a_ × _b_)/(√_■c_) = _x_. Set _c_ on B to _b_ an D, and under _a_ on C read _x_ on D.

To solve √((_a_^2 × _b_)/(_c_)) = _x_. Set _c_ on B to _a_ on D, and under _b_ on B read _x_ on D.

To solve (_a_^2 × _b_^2)/(_c_) = _x_. Set _c_ on B to _a_ on D, and over _b_ on C read _x_ on A.

To solve (_a_√_■b_)/(_c_) = _x_. Set _c_ on C to _b_ on A, and under _a_ on C read _x_ on D.

To solve ((_a_ × √_■b_)/(_c_))^2 = _x_. Set _c_ on C to _a_ on D, and over _b_ on B read _x_ on A.

HINTS ON EVALUATING EXPRESSIONS.

As a general rule, the use of cubes and higher powers should be avoided whenever possible. Thus, in the foregoing section, we recommend treating an expression of the form _a_√(_b_^3) as _a_ × _b_ × √_■b_; the magnitudes of the values thus met with are more easily appreciated by the beginner, and mistakes in estimating the large numbers involved in cubing are avoided.

EX.—7·3 × √(57^3) = 3140.

Set 1 on C to 57 on D; bring cursor to 57 on B (R.H., since 57 has an _even_ number of digits); bring 1 on C to cursor, and under 7·3 on C read 3140 on D. As a rough estimate we have √(57), about 8; 8 × 57, about 400; 400 × 7, gives 2800, showing the result consists of 4 figures.

An expression of the form _a_■(_b_^2), or _a_ _b_^■, is better dealt with by rearranging as _a_ × (_b_)/(■_b_).

EX.—3·64■(4·32^2) = 9·65.

Set cursor to 4·32 on A, and move the slide until 1·63 is found simultaneously under the cursor on B and on D under 1 on C; bring cursor to 1 on C; 4·32 on C to cursor, and _over_ 3·64 on D read 9·65 on C. (Note that in this case it is convenient to read the answer on the _slide_; see page 22). From the slide rule we know ■(4·32) = about 1·6; this into 4·32 is roughly 3; 3·64 × 3 is about 10, showing the answer to be 9·65.

Similarly products of the form _a_ × _b_^{■/■} are best dealt with as _a_ × _b_ × ■_b_.

Factorising expressions sometimes simplifies matters, as, for instance, in _x_^4 – _y_^4 = (_x_^2 + _y_^2)(_x_^2 – _y_^2). Here, working with the fourth powers involves large numbers and the troublesome determination of the number of digits in each factor; but squares are read on the rule at once, the number of digits is obvious, and, in general, the method should give a more accurate result. Take the expression, D_{1} = ■((D^4 – _d_^4)/(D)) giving the diameter D_{1} of a solid shaft equal in torsional strength to a hollow shaft whose external and internal diameters are D and _d_ respectively. Rearranging as D_{1} = ■(((D^2 + _d_^2)(D^2 – _d_^2))/(D)) and taking, as an example, D = 15 in. and _d_ = 7 in., we have D^2 + _d_^2 = 274 and D^2 – _d_^2 = 176; hence D_1 = ■((274 × 176)/(15)) = ■(3210) = 14·75 in.

Reversed Scale Notation.—With expressions of the form 1 – _x_, or 100 – _x_, it is often convenient to regard the scales as having their notation reversed, _i.e._, to read the scale backwards. When this is done the D scale is read as shown on the lower line—

Direct Notation 1 2 3 4 5 6 7 8 9 10 D Scale Reversed Notation 9 8 7 6 5 4 3 2 1 0

The new reading can be found by subtracting the ordinary reading from 1, 10, 100, etc., according to the value assigned to the R.H. index, but actually it is unnecessary to make this calculation, as with a little practice it is quite an easy matter to read both the main and subdivisions in the reversed order. Applications are found in plotting curves, trigonometrical formulæ, etc.

EX.—Find the per cent. of slip of a screw propeller from

100 – S = (10133V)/(PR)

taking the speed, V, as 15 knots, the pitch of the propeller, P, as 27 ft. 6 in., and the revolutions per minute, R, as 60.

Set 27·5 on B to 10133 on A (N.B.—Take the setting near the _centre_ index of A); bring the cursor to 15 on B and 60 on B to cursor. Reading the L.H. A scale backwards, the slip, S, = 8 per cent. is found on A over 10 on B.

Percentage Calculations.—To increase a quantity by _x_ per cent. we multiply by 100 + _x_; to diminish a quantity by _x_ per cent. we multiply by 100 – _x_. Hence, to add _x_ per cent., set 100 + _x_ on C to 1 on D and read new values on D under original values on C. To deduct _x_ per cent. read the D scale backwards from 10 and set R.H. index of C to _x_ per cent. so read. Then read as before.

GAUGE POINTS.

Special graduations, marking the position of constant factors which frequently enter into engineering calculations, are found on most slide rules. Usually the values of π = 3·1416 and (π)/(4) = 0·7854—the “gauge points” for calculating the circumference and area of a circle—are marked on the upper scales. The first should be given on the lower scales also. Marks _c_ and _c_^1 are sometimes found on the lower scales at 1·128 = √((4)/(π)) and at 3·568 = √((40)/(π)). These are useful in calculating the contents of cylinders and are thus derived:—Cubic contents of cylinder of diameter _d_ and length _l_ = (π)/(4)_d_^2_l_; substituting for (π)/(4) its reciprocal (4)/(π), the formula becomes (_d_^2)/(1·273 × _l_), and by taking the square root of the fractional part we have (_d_)/(1·128)^2 × _l_. This is now in a very convenient form, since by setting the gauge point _c_ on C to _d_ on D, we can read over _l_ on B the cubic contents on A. This example indicates the principle to be followed in arranging gauge points. Successive multiplication is avoided by substituting the reciprocal of the constant, thus bringing the expression into the form (_a_ × _b_)/(_c_), which, as we know, can be resolved by one setting of the slide. The advantage of dividing _d_ before squaring is also evident. The mark _c_^1 = _c_ × √(10) is used if it is necessary to draw the slide more than one-half its length to the right.

A gauge point, M, at 31·83 = (100)/(π) is found on the upper scales of some rules. Setting this point on B to the diameter of a cylinder on A, the circumference is read over 1 or 100 on B or the area of the curved surface over the length on B.

As another example of establishing a gauge point, we will take the formula for the theoretical delivery of pumps. If _d_ is the diameter of the plunger in inches, _l_ the length of stroke in feet, and Q the delivery in gallons, we have

Q = _d_^2 × (π)/(4) × _l_ × (12)/(277). (N.B.—277 cubic inches = 1 gallon.)

Multiplying out the constant quantities and taking its reciprocal, we readily transform the statement into Q = (_d_^2_l_)/(29·4) or ((_d_)/(5·42))^2 × _l_. Hence set gauge point 5·42 on C to _d_ on D and over length of stroke in feet on B, read delivery in gallons per stroke on A; or over piston speed in feet per minute on B, read theoretical delivery in gallons per minute on A.

Several examples of gauge points will be found in the section on calculating the weights of metal (see pages 59 and 60). In most cases their derivation will be evident from what has been said above. In the case of the weight of spheres, we have Vol. = 0·5236_d_^3, and this multiplied by the weight of 1 cubic inch of the material will give the weight W in lb. Hence for cast-iron, W = 0·5236 × _d_^3 × 0·26, which is conveniently transformed into W = (_d_ × _d_^2)/(7·35) as in the example on page 60.

With these examples no difficulty should be experienced in establishing gauge points for any calculation in which constant factors recur.

Marking Gauge Points.—The practice of marking gauge points by lines extending to the working edge of the scale is not to be recommended, as it confuses the ordinary reading of the scales. Generally speaking, gauge points are only required occasionally, and if they are placed clear of the scale to which they pertain, but near enough to show the connection, they can be brought readily into a calculation by means of the cursor. Usually there is sufficient margin above the A scale and below the D scale for various gauge points to be marked. Another plan consists in cutting two nicks in the upper and lower edges of the cursor near the centre and about ■ in. apart. These centre pieces, when bent out, form a tongue, which are in line with the cursor line and run nearly in contact with the square and bevelled edges of the rule respectively. A fine line in the tongue can then be set to gauge points marked on these two edge strips, the ordinary measuring graduations being removed, if desired, by a piece of fine sand-paper.

For gauge points marked on the face of the rule, the author prefers two fine lines drawn at 45°—thus, ✕—and crossing in the exact point which it is required to indicate. With the “cross” gauge point the meeting lines facilitate the placing of the cursor, and an exact setting is readily made.[7] All lines should be drawn in Indian ink with a very sharp drawing pen. For a more permanent marking the Indian ink may be rubbed up in glacial acetic acid or the special ink for celluloid may be used. If any difficulty is found in writing the distinguishing signs against the gauge point, the inscription may be formed by a succession of small dots made with a sharp pricker.

EXAMPLES IN TECHNICAL CALCULATIONS.

In order to illustrate the practical value of the slide rule, we now give a number of examples which will doubtless be sufficient to suggest the methods of working with other formulæ. A few of the rules give results which are approximate only, but in all cases the degree of accuracy obtained is well within the possible reading of the scales. In many cases the rules given may be modified, if desired, by varying the constants. In most of the examples the particular formula employed will be evident from the solution, but in a

few of the more complicated cases a separate statement has been given.

MENSURATION, ETC.

Given the chord _c_ of a circular arc, and the vertical height _h_, to find the diameter _d_ of the circle.

Set the height _h_ on B to half the chord on D, and over 1 on B read _x_ on A. Then _x_ + _h_ = _d_.

EX.—_c_ = 6; _h_ = 2; find _d_. Set 2 on B to 3 on D, and over 1 on B read 4·5 on A. Then 4·5 + 2 = 6·5 = _d_.

Given the radius of a circle _r_, and the number of degrees _n_ in an arc, to find the length _l_ of the arc.

Set _r_ on C to 57·3 on D, and over any number of degrees _n_ on D read the (approximate) length of the arc on C.

EX.—_r_ = 24; _n_ = 30; find _l_.

Set 24 on C to 57·3 on D, and over 30 on D read 12·56 = _l_ on C.

Given the diameter _d_ of a circle in _inches_, to find the circumference _c_ in _feet_.

Set 191 on C to 50 on D, and under any diameter in inches on C read circumference _c_, in feet on D.

EX.—Find the circumference in feet of a pulley 17 in. in diameter. Set 191 on C to 50 on D, and under 17 on C read 4·45 ft. on D.

Given the diameter of a circle, to find its area.

Set 0·7854 on B to 10 (centre index) on A and over any diameter on D read area on B.

When the rule has a special graduation line = 0·7854, on the right-hand scale of B, set this line to the R.H. index of A and read off as above. If only π is marked, set this special graduation on B to 4 on A.

On the C and D scales of some rules a gauge point marked _c_ will be found indicating $\sqrt{((4)/(\pi))} = 1{\cdot}1286$. In this case, therefore, set 1 on C to gauge point _c_ on D, and read area on A as above. If the gauge point _c_′ is used, divide the result by 10. Or set _c_ on C, to diameter on D, and over index of B read area on A. Cursors are supplied, having _two_ lines ruled on the glass, the interval between them being equal to $(4)/(\pi) = 1{\cdot}273$ on the A scale. In this case, if the right hand of the two cursor lines be set to the diameter on D, the _area_ will be read on A under the _left_-hand cursor line. For diameters less than 1·11 it is necessary to set the middle index of B to the L.H. index of A, reading the areas on the L.H. B scale. The confusion which in general work is sometimes caused by the use of two cursor lines might be obviated by making the left-hand line in two short lengths, each only just covering the scales.

Given diameter of circle _d_ in _inches_, to find area _a_ in square _feet_.

Set 6 on B to 11 on A, and over diameter in inches on D read area in square feet on B.

To find the surface in square feet of boiler flues, condenser tubes, heating pipes, etc., having given the diameter in inches and length in feet.

Find the circumference in feet as above and multiply by the length in feet.

EX.—Find the heating surface afforded by 160 locomotive boiler tubes 1¾in. in diameter and 12 ft. long.

Set 191 on C to 50 on D; bring cursor 1·75 on C, L.H. index of C to cursor; cursor to 12 on C; 1 on C to cursor; and under 160 on C read 880 sq. ft. of heating surface on D.

If the dimensions are in the same denomination and the rule has a gauge point M at 31·83 (= $(100)/(\pi)$), set this mark on B to diameter of cylinder on A, and read cylindrical surface on A over length on B.

To find the side _s_ of a square, equal in area to a given rectangle of length _l_ and breadth _b_.

Set R.H. or L.H. index of B to _l_ on A, and under _b_ on B read _s_ on D.

EX.—Find the side of a square equal in area to a rectangle in which _l_ = 31 ft. and _b_ = 5 ft.

Set the (R.H.) index of B to 31 on A, and under 5 on B read 12·45 ft. on D.

To find various lengths _l_ and breadths _b_ of a rectangle, to give a constant area _a_.

Invert the slide and set the index of ■ to the given area on D. Then opposite any length _l_ on ■ find the corresponding breadth _b_ on D.

EX.—Find the corresponding breadths of rectangular sheets, 16, 18, 24, 36, and 60 ft. long, to give a constant area of 72 sq. ft.

Set the R.H. index of ■ to 72 on D, and opposite 16, 18, 24, 36, and 60 on ■ read 4·5, 4, 3, 2, and 1·2 ft., the corresponding breadths on D.

To find the contents in cubic feet of a cylinder of diameter _d_ in inches and length _l_ in feet.

Find area in feet as before, and multiply by the length.

If dimensions are all in inches or feet, set the mark _c_ (= 1·128) on C to diameter on D and over length on B, read cubic contents on A.

To find the area of an ellipse.

Set 205 on C to 161 on D; bring cursor to length of major axis on C, 1 on C to cursor, and under length of minor axis on C read area on D.

EX.—Find the area of an ellipse the major and minor axes of which are 16 in. and 12 in. in length respectively.

Set 205 on C to 161 on D; bring cursor to 16 on C, 1 on C to cursor, and under 12 on C read 150·8 in. on D.

To find the surface of spheres.

Set 3·1416 on B to R.H. or L.H. index of A, and over diameter on D read by the aid of the cursor, the convex surface on B.

To find the cubic contents of spheres.

Set 1·91 on B to diameter on A, and over diameter on C read cubic contents on A.

WEIGHTS OF METALS.

To find the weight in lb. per lineal foot of square bars of metal.

Set index of B to weight of 12 cubic inches of the metal (_i.e._, one lineal foot, 1 square inch in section) on A, and over the side of the square in inches on C read weight in lb. on A.

EX.—Find the weight per foot length of 4½in. square wrought-iron bars.

Set middle index of B to 3·33 on A, and over 4½ on C read 67·5 lb. on A.

(N.B.—For other metals use the corresponding constant in column (2), below).

To find the weight in lb. per lineal foot of round bars.

Set R.H. or L.H. index of B to weight of 12 cylindrical inches of the metal on A (column (4), below), and opposite the diameter of the bar in inches on C, read weight in lb. per lineal foot on A.

EX.—Find the weight of 1 lineal foot of 2 in. round cast steel.

Set L.H. index of B to 2·68 on A, and over 2 on C read 10·7 lb. on A.

To find the weight of flat bars in lb. per lineal foot.

Set the breadth in inches on C to (1)/(weight of 12 cub. in.) of the metal (column (3), below) on D, and above the thickness on D read weight in lb. per lineal foot on C.

EX.—Find the weight per lineal foot of bar steel, 4½in. wide and ■in. thick.

Set 4·5 on C to 0·294 on D, and over 0·625 on D read 9·56 lb. per lineal foot on C.

To find the weight per square foot of sheet metal, set the weight per cubic foot of the metal (col. 1) on C to 12 on D, and

■■■

To find velocity in feet per second of a falling body, given the time of fall in seconds.

Set index on C to time of fall on D, and under 32·2 on C read velocity in feet per second on D.

To find velocity in feet per second, given distance fallen through in feet.

Set 1 on C to distance fallen through on A, and under 64·4 on B read velocity in feet per second on D.

EX.—Find velocity acquired by falling through 14 ft.

Set (R.H.) index of C to 14 on A, and under 64·4 on B read 30 ft. per second on D.

To find distance fallen through in feet in a given time.

Set index of C to time in seconds on D, and over 16·1 on B read distance fallen through in feet on A.

CENTRIFUGAL FORCE.

To find the centrifugal force of a revolving mass in lb.

Set 2940 on B to revolutions per minute on D; bring cursor to weight in lb. on B; index of B to cursor, and over radius in feet on B read centrifugal force in lb. on A.

To find the centrifugal stress in lb. per square inch, in rims of revolving wheels of cast iron.

Set 61·3 on C to the mean diameter of the wheel in feet on D, and over revolutions per minute on C read stress per square inch on A.

EX.—Find the stress per square inch in a cast-iron fly-wheel rim 8 ft. in diameter and running at 120 revolutions per minute.

Set 61·3 on C to 8 on D, and over 120 on C read 245 lb. per square inch on A.

THE STEAM ENGINE.

Given the stroke and number of revolutions per minute, to find the piston speed.

Set stroke in inches on C to 6 on D, and over number of revolutions on D read piston speed in feet per minute on C.

To find cubic feet of steam in a cylinder at cut-off, given diameter of cylinder and period of admission in inches.

Set 2200 on B to cylinder diameter on D, and over period of admission on B read cubic feet of steam on A.

EX.—Cylinder diameter 26 in., stroke 40 in., cut-off at ■ of stroke. Find cubic feet of steam used (theoretically) per stroke.

Set 2200 on B to 26 on D, and over 40 × ■ or 25 in. on B, read 7·68 cub. ft. on A, as the number of cubic feet of steam used per stroke.

Given the diameter of a cylinder in inches, and the pressure in lb. per square inch, to find the load on the piston in tons.

Set pressure in lb. per square inch on B to 2852 on A, and over cylinder diameter in inches on D read load on piston in tons on B.

EX.—Steam pressure 180 lb. per square inch; cylinder diameter, 42 in. Find load in tons on piston.

Set 180 on B to 2852 on A, and over 42 on D read 111 tons, the gross load, on B.

Given admission period and absolute initial pressure of steam in a cylinder, to find the pressure at various points in the expansion period (isothermal expansion).

Invert the slide and set the admission period, in inches, on ■ to the initial pressure on D; then under any point in the expansion stroke on ■ find the corresponding pressure on D.

EX.—Admission period 12 in., stroke 42 in., initial pressure 80 lb. per square inch. Find pressure at successive fifths of the expansion period.

Set 12 on ■ to 80 on D, and opposite 18, 24, 30, 36 and 42 in. of the whole stroke on ■ find the corresponding pressures on D:—53·3, 40, 32, 26·6 and 22·8 lb. per square inch.

To find the mean pressure constant for isothermally expanding steam, given the cut-off as a fraction of the stroke.

Find the logarithm of the ratio of the expansion _r_, by the method previously explained (page 46). Prefix the characteristic and to the number thus obtained, on D, set 1 on C. Then under 2·302 on C read _x_ on D. To _x_ + 1 on D set _r_ on C, and under index of C read mean pressure constant on D. The latter, multiplied by the initial pressure, gives the mean forward pressure throughout the stroke. (N.B.—Common log. × 2·302 = hyperbolic log.)

EX.—Find the mean pressure constant for a cut-off of ¼th, or a ratio of expansion of 4.

Set (L.H.) index of C to 4 on D, and on the reverse side of the slide read 0·602 on the logarithmic scale. The characteristic = 0; hence to 0·602 on D set (R.H.) index of C, and under 2·302 on C read 1·384 on D. Add 1, and to 2·384 thus obtained on D set _r_ (= 4) on C, and under 1 on C read 0·596, the mean pressure constant required.

Mean pressure constants for the most usual degrees of cut-off are given below:—

Cut-off in fractions of stroke Mean pressure constant ¾ 0·968 ■/■■ 0·952 ■ 0·934 ■ 0·919 ■ 0·913 ½ 0·846 ■ 0·766 ■ 0·750 ■ 0·699 ⅜■■ 0·664 ¼ 0·596 ■ 0·522 ■ 0·465 ■ 0·421 ■ 0·385 ■ 0·355 ■ 0·330 ⅛■■ 0·309 ⅛■■ 0·290 ⅛■■ 0·274 ⅛■■ 0·260 ⅛■■ 0·247 ⅛■■ 0·236

To find mean pressure:—Set 1 on C to constant on D, and under initial pressure on C read mean pressure on D.

Given the absolute initial pressure, length of stroke, and admission period, to find the absolute pressure at any point in the expansion period, it being assumed that the steam expands adiabatically. (P_{2} = (P_{1})/(R^{1■/■}) in which P_{1} = initial pressure and P_{2} the pressure corresponding to a ratio of expansion R.)

Set L.H. index of C to ratio of expansion on D, and read on the back of the slide the decimal of the logarithm. Add the characteristic, and to the number thus obtained on D set 9 on C, and read off the value found on D under the index of C. Set this number on the logarithmic scale to the index mark, in the opening on the back of the rule, and under L.H. index of C read the value of R^{1■/■} on D. The initial pressure divided by this value gives the corresponding pressure due to the expansion.

EX.—Absolute initial pressure 120 lb. per square inch; stroke, 4 ft.; cut-off ¼. Find the respective pressures when ½ and ¾ths of the stroke have been completed.

In the first case R = 2. Therefore setting the L.H. index of C to 2 on D, we find the decimal of the logarithm on the back of the slide to be 0·301. The characteristic is 0, so placing 9 on C to 0·301 on D, we read 0·334 as the value under the R.H. index of C. (N.B.—In locating the decimal point it is to be observed that the log. of R has been multiplied by 10, in accordance with the terms of the above expression.) Setting this number on the logarithmic scale to the back index, the value of R^{1■/■} is found on D, under the L.H. index of C, to be 2·16. Setting 120 on C to this value, it is found that the pressure at ½ stroke, read on C over the R.H. index of D, is 55·5 lb. per square inch. In a similar manner, the pressure when ¾ths of the stroke is completed is found to be 35·4 lb. per square inch.

For other conditions of expanding steam, or for gas or air, the method of procedure is similar to the above.

To find the horse-power of an engine, having given the mean _effective_ pressure, the cylinder diameter, stroke, and number of revolutions per minute.

To cylinder diameter on D set 145 on C; bring cursor to stroke in feet on B, 1 on B to cursor, cursor to number of revolutions on B, 1 on B to cursor, and over mean effective pressure on B find horse-power on A.

(N.B.—If stroke is in inches, use 502 in place of 145 given above.)

EX.—Find the indicated horse-power, given cylinder diameter 27 in., mean effective pressure 38 lb. per square inch, stroke 32 in., revolutions 57 per minute.

Set 502 on C to 27 on D, bring cursor to 32 on B, 1 on B to cursor, cursor to 57 on B, 1 on B to cursor, and over 38 on B read 200 I.H.P. on A.

To determine the horse-power of a compound engine, invert the slide and set the diameter of the _high_-pressure cylinder on ■ to the cut-off in that cylinder on A. Use the number then found on A over the diameter of the _low_-pressure cylinder on ■ as the cut-off in that cylinder, working with the same pressure and piston speed, and calculate the horse-power as for a single cylinder.

To find the cylinder ratio in compound engines, invert the slide and set index of ■ to diameter of the low-pressure cylinder on D. Then over the diameter of the high-pressure cylinder on C, read cylinder ratio on A.

EX.—Diameter of high-pressure cylinder 7¾in., low-pressure 15 in. Find cylinder ratio.

Set index on ■ to 15 on D, and over 7·75 on ■ read 3·75, the required ratio, on A.

The cylinder ratios of triple or quadruple-expansion engines may be similarly determined.

EX.—In a quadruple-expansion engine, the cylinders are 18, 26, 37, and 54 inches in diameter. Find the respective ratios of the high, first intermediate, and second intermediate cylinders to the low-pressure.

Set (R.H.) index of ■ to 54 on D, and over 18, 26, and 37 on ■ read 9, 4·31, and 2·13, the required ratios, on A.

Given the mean effective pressures in lb. per square inch in each of the three cylinders of a triple-expansion engine, the I.H.P. to be developed in each cylinder, and the piston speed, to find the respective cylinder diameters.

Set 42,000 on B to piston speed on A; bring cursor to mean effective pressure in low-pressure cylinder on B, index of B to cursor, and under I.H.P. on A read low-pressure cylinder diameter on C. To find the diameters of the high-pressure and intermediate-pressure cylinders, invert the slide and place the mean pressure in the low-pressure cylinder on ■ to the diameter of that cylinder on D. Then under the respective mean pressures on ■ read corresponding cylinder diameters on D.

EX.—The mean effective pressures in the cylinders of a triple-expansion engine are:—L.P., 10·32; I.M.P., 27·5; and H.P., 77·5 lb. per square inch. The piston speed is 650 ft. per minute, and the I.H.P. developed in each cylinder, 750. Find the cylinder diameters.

Set 42,000 on B to 650 on A, and bring cursor to 10·32 on B. Bring index of B to cursor, and under 750 on A read 68·5 in. on C, the L.P. cylinder diameter. Invert the slide, and placing 10·32 on ■ to 68·5 on D, read, under 27·5 on ■, the I.M.P. cylinder diameter = 42 in., on D; also under 77·5 on ■ read the H.P. cylinder diameter = 25 in., on D.

To compute brake or dynamometrical horse-power.

Set 525 on C to the total weight in lb. acting at the end of the lever (or pull of spring balance in lb.) on D; set cursor to length of lever in feet on C, bring 1 on C to cursor, and under number of revolutions per minute on C find brake horse-power on D.

Given cylinder diameter and piston speed in feet per minute, to find diameter of steam pipe, assuming the maximum velocity of the steam to be 6000 ft. per minute.

Set 6000 on B to cylinder diameter on D, and under piston speed on B read steam pipe diameter on D.

Given the number of revolutions per minute of a Watt governor, to find the vertical height in inches, from the plane of revolution of the balls to the point of suspension.

Set revolutions per minute on C to 35,200 on A, and over index of B read height on A.

Given the weight in lb. of the rim of a cast-iron fly-wheel, to find the sectional area of the rim in square inches.

Set the mean diameter of the wheel in feet on C to 0·102 on D, and under weight of rim on C find area on D.

Given the consumption of coal in tons per week of 56 hours, and the I.H.P., to find the coal consumed per I.H.P. per hour.

Set I.H.P. on C to 40 on D, and under weekly consumption on C read lb. of coal per I.H.P., per hour on D.

EX.—Find coal used per I.H.P. per hour, when 24 tons is the weekly consumption for 300 I.H.P.

Set 300 on C to 40 on D, and under 24 on C read 3·2 lb. per I.H.P. per hour on D.

(N.B.—For any other number of working hours per week divide 2240 by the number of working hours, and use the quotient in place of 40 as above.)

To find the tractive force of a locomotive.

Set diameter of driving wheel in inches on B to diameter of cylinder in inches on D, and over the stroke in inches on B read on A, tractive force in lb. for each lb. of effective pressure on the piston.

STEAM BOILERS.

To find the bursting pressure of a cylindrical boiler shell, having given the diameter of shell and the thickness and ultimate strength of the material.

Set the diameter of the shell in inches on C to twice the thickness of the plate on D, and under strength of material per square inch on C read bursting pressure in lb. per square inch on D.

EX.—Find the bursting pressure of a cylindrical boiler shell 7 ft. 6 in. in diameter, with plates ½in. thick, assuming an ultimate strength of 50,000 lb. per square inch.

Set 90 on C to 1·0 on D, and under 50,000 on C find 555 lb. on D.

To find working pressure for Fox's corrugated furnaces by Board of Trade rule.

Set the least outside diameter in inches on C to 14,000 on D, and under thickness in inches on C read working pressure on D in lb. per square inch.

To find diameter _d_ in inches, of round steel for safety valve springs by Board of Trade rule.

Set 8000 on C to load on spring in lb. on D, and under the mean diameter of the spring in inches on C read _d_^3 on D. Then extract the cube root as per rule.

SPEED RATIOS OF PULLEYS, ETC.

Given the diameter of a pulley and its number of revolutions per minute, to find the circumferential velocity of the pulley or the speed of ropes, belts, etc., driven thereby.

Set diameter of pulley in inches on C to 3·82 on D, and over revolutions per minute on D read speed in feet per minute on C.

EX.—Find the speed of a belt driven by a pulley 53 in. in diameter and running at 180 revolutions per minute.

Set 53 on C to 3·82 on D, and over 180 on D read 2500 ft. per minute on C.

EX.—Find the speed of the pitch line of a spur wheel 3 ft. 6 in. in diameter running at 60 revolutions per minute.

Set 42 in. on C to 3·82 on D, and over 60 on D read 660 ft. per minute on C.

Given diameter and number of revolutions per minute of a driving pulley, and the diameter of the driven pulley, to find the number of revolutions of the latter.

Invert the slide and set diameter of driving pulley on ■ to given number of its revolutions on D; then opposite diameter of any driven pulley on ■ read its number of revolutions on D.

EX.—Diameter of driving pulley 10 ft.; revolutions per minute 55; diameter of driven pulley 2 ft. 9 in. Find number of revolutions per minute of latter.

Set 10 on ■ to 55 on D, and opposite 2·75 on ■ read 200 revolutions on D.

BELTS AND ROPES.

To find the ratio of tensions in the two sides of a belt, given the coefficient of friction between belt and pulley μ and the number of degrees θ in the arc of contact (log. $R = (\mu\theta)/(132)$).

Set 132 on C to the coefficient of friction on D, and read off the value found on D under the number of degrees in the arc of contact on C. Place this value on the scale of equal parts on the back of the slide, to the index mark in the aperture, and read the required ratio on D under the L.H. index of C.

EX.—Find the tension ratio in a belt, assuming a coefficient of friction of 0·3 and an arc of contact of 120 degrees.

Set 132 on C to 0·3 on D, and under 120 on C read 0·273. Place this on the scale to the index on the back of the rule, and under the L.H. index C read 1·875 on D, the required ratio.

Given belt velocity and horse-power to be transmitted, to find the requisite width of belt, taking the effective tension at 50 lb. per inch of width.

Set 660 on C to velocity in feet per minute on D, and opposite horse-power on D find width of belt in inches on C.

Given velocity and width of belt, to find horse-power transmitted.

Set 660 on C to velocity on D, and under width on C find horse-power transmitted on D.

(N.B.—For any other effective tension, instead of 660 use as a gauge point:—33,000 ÷ tension.)

Given speed and diameter of a cotton driving rope, to find power transmitted, disregarding centrifugal action, and assuming an effective working tension of 200 lb. per square inch of rope.

Set 210 on B to 1·75 on D, and over speed in feet per minute on B read horse-power on A.

EX.—Find the power transmitted by a 1¾in. rope running at 4000 ft. per minute.

Set 210 on B to 1·75 on D, and over 4000 on B read 58·3 horse-power on A.

Find the “centrifugal tension” in the previous example, taking the weight per foot of the rope as = 0·27_d_^2.

Set 655 on C to the diameter, 1·75 in., on D, and over the speed, 4000 ft. on C, read centrifugal tension = 114 lb. on A.

SPUR WHEELS.

Given diameter and pitch of a spur wheel, to find number of teeth.

Set pitch on C to π (3·1416) on D, and under any diameter on C read number of teeth on D.

Given diameter and number of teeth in a spur wheel, to find the pitch.

Set diameter on C to number of teeth on D, and read pitch on C opposite 3·1416 on D.

Given the distance between the centres of a pair of spur wheels and the number of revolutions of each, to determine their diameters.

To twice the distance between the centres on D, set the sum of the number of revolutions on C, and under the revolutions of each wheel on C find the respective wheel diameters on D.

EX.—The distance between the centres of two spur wheels is 37·5 in., and they are required to make 21 and 24 revolutions in the same time. Find their respective diameters.

Set 21 + 24 = 45 on C to 75 (or 37·5 × 2) on D, and under 21 and 24 on C find 35 and 40 in. on D as the respective diameters.

To find the power transmitted by toothed wheels, given the pitch diameter _d_ in inches, the number of revolutions per minute _n_, and the pitch _p_ in inches, by the rule, H.P. = (_n_ _d_ _p_^2)/(400).

Set 400 on B to pitch in inches on D; set cursor to d on B, 1 on B to cursor, and over any number of revolutions n on B read power transmitted on A.

EX.—Find the horse-power capable of being transmitted by a spur wheel 7 ft. in diameter, 3 in. pitch, and running at 90 revolutions per minute.

Set 400 on B to 3 on D; bring cursor to 84 in. on B, 1 on B to cursor, and over 90 revolutions on B read 170, the horse-power transmitted, on A.

SCREW-CUTTING.

Given the number of threads per inch in the guide screw, to find the wheels to cut a screw of given pitch.

Set threads per inch in guide screw on C, to the number of threads per inch to be cut on D. Then opposite any number of teeth in the wheel on the mandrel on C, is the number of teeth in the wheel to be placed on the guide screw on D.

STRENGTH OF SHAFTING.

Given the diameter _d_ of a steel shaft, and the number of revolutions per minute _n_, to find the horse-power from:—

H.P. = _d_^3 × _n_ × 0·02.

Set 1 on C to _d_ on D, and bring cursor to _d_ on B. Bring 50 on B to cursor, and over number of revolutions on B read H.P. on A.

EX.—Find horse-power transmitted by a 3 in. steel shaft at 110 revolutions per minute.

Set 1 on C to 3 on D, and bring cursor to 3 on B. Bring 50 on B to cursor, and over 110 on B read 59·4 horse-power on A.

Given the horse-power to be transmitted and the number of revolutions of a steel shaft, to find the diameter.

Set revolutions on B to horse-power on A, and bring cursor to 50 on B. Then move the slide until the same number is found on B under the cursor that is simultaneously found on D under the index of C. This number is the diameter required.

To find the deflection _k_ in inches, of a round steel shaft of diameter _d_, under a uniformly distributed load in lb. _w_, and supported by bearings, the centres of which are _l_ feet apart (_k_ = (_w_ _l_^3)/(78,000_d_^4)).

Modifying the form of this expression slightly, we proceed as follows:—Set _d_ on C to _l_ on D, and bring the cursor to the same number on B that is found on D under the index of C. Bring _d_ on B to cursor, cursor to _w_ on B, 78,800 on B to cursor, and read deflection on A over index of B.

EX.—Find the deflection in inches of a round steel shaft 3½in. diameter, carrying a uniformly distributed load of 3200 lb., the distance apart of the centres of support being 9 ft.

Set 3·5 on C to 9 on D, and read 2·57 on D, under the L.H. index of C. Set cursor to 2·57 on B, and bring 3·5 on B to cursor, cursor to 3200 on B, 78,000 on B to cursor, and over L.H. index of B read 0·199 in., the required deflection on A.

To find the diameter of a shaft subject to twisting only, given the twisting moment in inch-lb. and the allowable stress in lb. per square inch.

Set the stress in lb. per square inch on B to the twisting moment in inch-lb. on A, and bring cursor to 5·1 on B. Then move the slide until the same number is found on B under the cursor that is simultaneously found on D under the index of C.

EX.—A steel shaft is subjected to a twisting moment of 2,700,000 inch-lb. Determine the diameter if the allowable stress is taken at 9000 lb. per square inch.

Set 9000 on B to 2,700,000 on A, and bring the cursor to 5·1 on B. Moving the slide to the left, it is found that when 11·51 on the R.H. scale of B is under the cursor, the L.H. index of C is opposite 11·51 on D. This, then, is the required diameter of the shaft.

(N.B.—The rules for the scales to be used in finding the cube root (page 42) must be carefully observed in working these examples.)

MOMENTS OF INERTIA.

To find the moment of inertia of a square section about an axis formed by one of its diagonals ($I = (s^4)/(12)$).

Set index of C to the length of the side of square _s_ on D; bring cursor to _s_ on C, 12 on B to cursor, and over index of B read moment of inertia on A.

To find the moment of inertia of a rectangular section about an axis parallel to one side and perpendicular to the plane of bending.

Set index of C to the height or depth _h_ of the section, and bring cursor to _h_ on B. Set 12 on B to cursor, and over breadth _b_ of the section on B read moment of inertia on A.

EX.—Find the moment of inertia of a rectangular section of which _h_ = 14 in. and _b_ = 7 in.

Set index of C to 14 on D, and cursor to 14 on B. Bring 12 on B to cursor, and over 7 on B read 1600 on A.

DISCHARGE FROM PUMPS, PIPES, ETC.

To find the theoretical delivery of pumps, in gallons per stroke.

Set 29·4 on B to the diameter of the plunger in inches on D, and over length of stroke in feet on B read theoretical delivery in gallons per stroke on A.

(N.B.—A deduction of from 20 to 40 per cent. should be made to allow for slip.)

To find loss of head of water in feet due to friction in pipes (Prony's rule).

Set diameter of pipe in feet on B to velocity of water in feet per second on D and bring cursor to 2·25 on B; bring 1 on B to cursor, and over length of pipe in miles on B, read loss of head of water in feet, on A.

To find velocity in feet per second, of water in pipes (Blackwell's rule).

Set 2·3 on B to diameter of pipe in feet on A, and under inclination of pipe in feet per mile on B read velocity in feet per second on D.

To find the discharge over weirs in cubic feet per minute and per foot of width. (Discharge = $214\sqrt{(h^3)}$)

Set 0·00467 on C to the head in feet _h_ on D, and under _h_ on B read discharge on D.

To find the theoretical velocity of water flowing under a given head in feet.

Set index of B to head in feet on A, and under 64·4 on B read theoretical velocity in feet per second on D.

HORSE-POWER OF WATER WHEELS.

To find the effective horse-power of a Poncelet water wheel.

Set 880 on C to cubic feet of flow of water per minute on D, and under height of fall in feet on C, read effective horse-power on D.

For breast water wheels use 960, and for overshot wheels 775, in place of 880 as above.

ELECTRICAL ENGINEERING.

To find the resistance per mile, in ohms, of copper wire of high conductivity, at 60° F. the diameter being given in mils. (1 mil. = 0·001 in.).

Set diameter of wire in mils. on C to 54,900 on A, and over R.H. or L.H. index of B read resistance in ohms on A.

EX.—Find the resistance per mile of a copper wire 64 mils. in diameter.

Set 64 on C to 54,900 on A, and over R.H. index of B read 13·4 ohms on A.

To find the weight of copper wire in lb. per mile.

Set 7·91 on C to diameter of wire in mils. on D, and over index of B read weight per mile on A.

Given electromotive force and current, to find electrical horse-power.

Set 746 on C to electromotive force in volts on D, and under current in ampères on C read electrical horse-power on D.

Given the resistance of a circuit in ohms and current in ampères, to find the energy absorbed in horse-power.

Set 746 on B to current on D, and over resistance on B read energy absorbed in H.P. on A.

EX.—Find the H.P. expended in sending a current of 15 ampères through a circuit of 220 ohms resistance.

Set 746 on B to 15 on D, and over 220 on B read 66·3 H.P. on A.

COMMERCIAL.

To add on percentages.

Set 100 on C to 100 + given percentage on D, and under original number on C read result on D.

To deduct percentages.

Set R.H. index of C to 100 – the given percentage on D, and under original number on C read result on D.

EX.—From £16 deduct 7½ per cent.

Set 10 on C to 92·5 on D and under 16 on C, read 14·8 = £14, 16s. on D.

To calculate simple interest.

Set 1 on C to rate per cent. on D; bring cursor to period on C and 1 on C to cursor. Then opposite any sum on C find simple interest on D.

For interest per annum.

Set R.H. index on C to rate on D, and opposite principal on C read interest on D.

EX.—Find the amount with simple interest of £250 at 8 per cent., and for a period of 1 year and 9 months.

Set 1 on C to 8 on D; bring cursor to 1·75 on C, and 1 on C to cursor; then opposite 250 on C read £35, the interest, on D. Then 250 + 35 = £285 = the amount.

To calculate compound interest.

Set the L.H. index of C to the amount of £1 at the given rate of interest on D, and find the logarithm of this by reading on the reverse side of the rule, as explained on page 46. Multiply the logarithm, so found, by the period, and set the result, on the scale of equal parts, to the index on the under-side of the rule; then opposite any sum on C read the amount (including compound interest) on D.

EX.—Find the amount of £500 at 5 per cent. for 6 years, with compound interest.

Set L.H. index of C to £1·05 on D, and read at the index on the scale of equal parts on the under-side of rule, 0·0212. Multiply by 6, we obtain 0·1272, which, on the scale of equal parts, is placed to the index in the notch at the end of the rule. Then opposite 500 on C read £670 on D, the amount required, including compound interest.

MISCELLANEOUS CALCULATIONS.

To calculate percentages of compositions.

Set weight (or volume) of sample on C, to weight (or volume) of substance considered, on D; then under index of C read required percentage on D.

EX.—A sample of coal weighing 1·25 grms. contains 0·04425 grm. of ash. Find the percentage of ash.

Set 1·25 on C to 0·04425 on D, and under index on C read 3·54, the required percentage of ash on D.

Given the steam pressure P and the diameter _d_ in millimetres, of the throat of an injector, to find the weight W, of water delivered in lb. per hour from W = (_d_^2√■P)/(0·505).

Set 0·505 on C to P on A; bring cursor to _d_ on C and index of C to cursor. Then under _d_ on C read delivery of water on D.

To find the pressure of wind per square foot, due to a given velocity in miles per hour.

Set 1 on B to 2 on A, and over the velocity in miles per hour on D read pressure in lb. per square foot on B.

To find the kinetic energy of a moving body.

Set 64·4 on B to velocity in feet per second on D, and over weight of body in lb. on B read kinetic energy or accumulated work in foot-lb. on A.

TRIGONOMETRICAL APPLICATIONS

Scales.—Not the least important feature of the modern slide rule is the provision of the special scales on the under-side of the slide, and by the use of which, in conjunction with the ordinary scales on the rule, a large variety of trigonometrical computations may be readily performed.

Three scales will be found on the reverse or under-side of the slide of the ordinary Gravêt or Mannheim rule. One of these is the evenly-divided scale or scale of equal parts referred to in previous sections, and by which, as explained, the decimal parts or mantissæ of logarithms of numbers may be obtained. Usually this scale is the centre one of the three, but in some rules it will be found occupying the lowest position, in which case some little modification of the following instructions will be necessary. The requisite transpositions will, however, be evident when the purposes of the scales are understood. The upper of the three scales, usually distinguished by the letter S, is a scale giving the logarithms of the sines of angles, and is used to determine the natural sines of angles of from 35 minutes to 90 degrees. The notation of this scale will be evident on inspection. The main divisions 1, 2, 3, etc., represent the degrees of angles; but the values of the subdivisions differ according to their position on the scale. Thus, if any primary space is subdivided into 12 parts, each of the latter will be read as 5 minutes (5′), since 1° = 60′.

Sines of Angles.—To find the sine of an angle the slide is placed in the groove, with the under-side uppermost, and the end division lines or indices on the slide, coinciding with the right and left indices of the A scale. Then over the given angle on S is read the value of the sine of the angle on A. If the result is found on the left scale of A (1 to 10), the logarithmic characteristic is –2; if it is found on the right-hand side (10 to 100), it is –1. In other words, results on the right-hand scale are prefixed by the decimal point only, while those on the left-hand scale are to be preceded by a cypher also. Thus:—

Sine 2° 40′ = 0·0465; sine 15° 40′ = 0·270.

Multiplication and division of the sines of angles are performed in the same manner as ordinary calculations, excepting that the slide has its under-face placed uppermost, as just explained. Thus to multiply sine 15° 40′ by 15, the R.H. index of S is brought to 15 on A, and opposite 15° 40′ on S is found 4·05 on A. Again, to divide 142 by sine 16° 30′, we place 16° 30′ on S to 142 on A, and over R.H. index of S read 500 on A.

The rules for the number of integers in the results are thus determined: Let N be the number of integers in the multiplier M or in the dividend D. Then the number of integers P, in the product or Q, in the quotient are as follows:—

When the result is found to the right of M or D, ■P = N – 2■Q = N and in the same scale ■ ■ When the result is found to the right of M or D, ■P = N – 1■Q = N + 1 and in the other scale ■ ■ When the result is found to the left of M or D, and■P = N – 1■Q = N + 1 in the other scale ■ ■ When the result is found to the left of M or D, and■P = N ■Q = N + 2 in the same scale ■ ■

If the division is of the form (20° 30′)/(50), the result cannot be read off directly on the face of the rule. Thus, if in the above example 20° 30′ on S, is placed to agree with 50 on the right-hand scale of A, the result found on S under the R.H. index of A is 44° 30′. The required numerical value can then be found: (1) By placing the slide with all indices coincident when opposite 44° 30′ on S will be found 0·007 on A; or (2) In the ordinary form of rule, by reading off on the scale B opposite the index mark in the opening on the under-side of the rule. The above rules for the number of integers in the quotient do not apply in this case.

If it is required to find the sine of an angle simply, this may be done with the slide in its ordinary position, with scale B under A. The given angle on scale S is then set to the index on the under-side of the rule, and the value of the sine is read off on B under the right index of A.

Owing to the rapidly diminishing differences of the values of the sines as the upper end of the scale is approached, the sines of angles between 60° and 90° cannot be accurately determined in the foregoing manner. It is therefore advisable to calculate the value of the sine by means of the formula:

Sine $\theta = 1 - 2 \sin^2 (90 - \theta)/(2)$.

To determine the value of $\sin^2 (90 - \theta)/(2)$. With the slide in the normal position, set the value of $(90 - \theta)/(2)$. on S to the index on the under-side of the rule, and read off the value _x_ on B under the R.H. index of A. Without moving the slide find _x_ on A, and read under it on B the value required.

EX.—Find value of sine 79° 40′.

Sine 79° 40′ = 1 – 2sin^2 5° 10′.

But sine 5° 10′ = 0·0900, and under this value on A is 0·0081 on B. Therefore sine 79° 40′ = 1 – 0·0162 = 0·9838.

The sines of very small angles, being very nearly proportional to the angles themselves, are found by direct reading. To facilitate this, some rules are provided with two marks, one of which, a single accent (′), corresponds to the logarithm of (1)/(sine 1′) and is found at the number 3438. The other mark—a double accent (″)—corresponds to the logarithm of (1)/(sine 1″) and is found at the number 206,265. In some rules these marks are found on either the A or the B scales; sometimes they are on both. In either case the angle on the one scale is placed so as to coincide with the significant mark on the other, and the result read off on the first-named scale opposite the index of the second.

In sines of angles under 3″, the number of integers in the result is –5; while it is –4 for angles from 3″ to 21″; –3 from 21″ to 3′ 27″; and –2 from 3′ 27″ to 34′ 23″.

EX.—Find sine 6′.

Placing the significant mark for minutes coincident with 6, the value opposite the index is found to be 175, and by the rule above this is to be read 0·00175. For angles in seconds the other significant mark is used; while angles expressed in minutes and seconds are to be first reduced to seconds. Thus, 3′ 10″ = 190″.

Tangents of Angles.—There remains to be considered the third scale found on the back of the slide, and usually distinguished from the others by being lettered T. In most of the more recent forms of rule this scale is placed near the lower edge of the slide, but in some arrangements it is found to be the centre scale of the three. Again, in some rules this scale is figured in the same direction as the scale of sines—viz., from left to right,—while in others the T scale is reversed. In both cases there is now usually an aperture formed in the back of the left extremity of the rule, with an index mark similar to that already referred to in connection with the scale of sines. Considering what has been referred to as the more general arrangement, the method of determining the tangents of angles may be thus explained:—

The tangent scale will be found to commence, in some rules, at about 34′, or, precisely, at the angle whose tangent is 0·01. More usually, however, the scale will be found to commence at about 5° 43′, or at the angle whose tangent is 0·1. The other extremity of the scale corresponds in all cases to 45°, or the angle whose tangent is 1. This explanation will suggest the method of using the scale, however it may be arranged. If the graduations commence with 34′, the T scale is to be used in conjunction with the right and left scales of A; while if they commence with 5° 43′ it is to be used in conjunction with the D scale.

In the former case the slide is to be placed in the rule so that the T scale is adjacent to the A scales, and, with the right and left indices coinciding, when opposite any angle on T will be found its tangent on A. From what has been said above, it follows that the tangents read on the L.H. scale of A have values extending from 0·01 to 0·1; while those read on the R.H. scale of A have values from 0·1 to 1·0. Otherwise expressed, to the values of any tangent read on the L.H. scale of A a cypher is to be prefixed; while if found on the R.H. scale, it is read directly as a decimal.

EX.—Find tan. 3° 50′.

Placing the slide as directed, the reading on A opposite 3° 50′ on T is found to be 67. As this is found on the L.H. scale of A, it is to be read as 0·067.

EX.—Find tan. 17° 45′.

Here the reading on A opposite 17° 45′ on T is 32, and as it is found on the R.H. scale of A it is read as 0·32.

As in the case of the scale of sines, the tangents may be found without reversing the slide, when a fixed index is provided in the back of the rule for the T scale.

We revert now to a consideration of those rules in which a single tangent scale is provided. It will be understood that in this case the slide is placed so that the scale T is adjacent to the D scale, and that when the indices of both are placed in agreement, the value of the tangent of any angle on T (from 5° 43′ to 45°) may be read off on D, the result so found being read as wholly decimal. Thus tan. 13° 20′ is read 0·237.

If a back index is provided, the slide is used in its normal position, when, setting the angle on the tangent scale to this index, the result can be read on C over the L.H. index of D.

The tangents of angles above 45° are obtained by the formula: Tan. $\theta = (1)/(\tan.\ (90 - \theta))$. For all angles from 45° to (90° – 5° 43′) we proceed as follows:—Place $(90 - \theta)$ on T to the R.H. index of D, and read tan. θ on D under the L.H. index of T. The first figure in the value thus obtained is to be read as an integer. Thus, to find tan. 71° 20′ we place 90° – 71° 20′ = 18° 40′ on T, to the R.H. index of D, and under the L.H. index of T read 2·96, the required tangent.

The tangents of angles less than 40′ are sensibly proportional to the angles themselves, and as they may therefore be considered as sines, their value is determined by the aid of the single and double accent marks on the sine scale, as previously explained. The rules for the number of integers are the same as for the sines.

Multiplication and division of tangents may be quite readily effected.

EX.—Tan. 21° 50′ × 15 = 6.

Set L.H. index of T to 15 on D, and under 21° 50′ on T read 6 on D.

EX.—Tan. 72° 40′ × 117 = 375.

Set (90° – 72° 40′) = 17° 20′ on T to 117 on D, and under R.H. index of T read 375 on D.

Cosines of Angles.—The cosines of angles may be determined by placing the scale S with its indices coinciding with those of A, and when opposite $(90 - \theta)$ on S is read cos. θ on A. If the result is read on the L.H. scale of A, a cypher is to be prefixed to the value read; while if it is read on the R.H. scale of A, the value is read directly as a decimal. Thus, to determine cos. 86° 30′ we find opposite (90° – 86° 30′) = 3° 30′ on S, 61° on A, and as this is on the L.H. scale the result is read 0·061. Again, to find cos. 59° 20′ we read opposite (90° – 59° 20′) or 30° 40′ on S, 51 on A, and as this is found on the R.H. scale of A, it is read 0·51.

In finding the cosines of small angles it will be seen that direct reading on the rule becomes impossible for angles of less than 20°. It is advisable in such cases to adopt the method described for determining the _sines_ of the _large_ angles of which the complements are sought.

Cotangents of Angles.—From the methods of finding the tangents of angles previously described, it will be apparent that the cotangents of angles may also be obtained with equal facility. For angles between 5° 45′ and 45°, the procedure is the same as that for finding tangents of angles greater than 45°. Thus, the angle on scale T is brought to the R.H. index of D, and the cotangent read

off on D under the L.H. index of T. The first figure of the result so found is to be read as an integer.

If the angle (θ) lies between 45° and 84° 15′, the slide is placed so that the indices of T coincide with those of D, and the result is then read off on D opposite ($90 - \theta$) on T. In this case the value is wholly decimal.

Secants of Angles.—The secants of angles are readily found by bringing ($90 - \theta$) on S to the R.H. index of A and reading the result on A over the L.H. index of S. If the value is found on the L.H. scale of A, the first figure is to be read as an integer; while if the result is read on the R.H. scale of A, the first _two_ figures are to be regarded as integers.

Cosecants of Angles.—The cosecants of angles are found by placing the angle on S to the R.H. index of A, and reading the value found on A over the L.H. index of S. If the result is read on the L.H. scale of A, the first figure is to be read as an integer; while if the result is found on the R.H. scale of A, the first _two_ figures are to be read as integers.

It will be noted that some of the rules here given for determining the several trigonometrical functions of angles apply only to those forms of rules in which a single scale of tangents T is used, reading from left to right. For the other arrangements of the scale, previously referred to, some slight modification of the method of procedure in finding the tangents and cotangents of angles will be necessary; but as in each case the nature and extent of this modification is evident, no further directions are required.

THE SOLUTION OF RIGHT-ANGLED TRIANGLES.

From the foregoing explanation of the manner of determining the trigonometrical functions of angles, the methods of solving right-angled triangles will be readily perceived, and only a few examples need therefore be given.

Let _a_ and _b_ represent the sides and _c_ the hypothenuse of a right-angled triangle, and _a_° and _b_° the angles opposite to the sides. Then of the possible cases we will take

(1.) Given _c_ and _a_°, to find _a_, _b_, and _b_°.

The angle _b_° = 90 – _a_°, while _a_ = _c_ sin _a_° and _b_ = _c_ sin _b_°. To find _a_, therefore, the index of S is set to _c_ on A, and the value of _a_ read on A opposite _a_° on S. In the same manner the value of _b_ is obtained.

EX.—Given in a right-angled triangle _c_ = 9 ft. and _a_° = 30°. Find _a_, _b_, and _b_°.

The angle _b_° = 90 – 30 = 60°. To find _a_, set R.H. index of S to 9 on A, and over 30° on S read _a_ = 4·5 ft. on A. Also, with the slide in the same position, read _b_ = 7·8 ft. [7·794] on A over 60° on S.

(2.) Given _a_ and _c_, to determine _a_°, _b_°, and _b_.

In this case advantage is taken of the fact that in every triangle the sides are proportional to the sines of the opposite angles. Therefore, as in this case the hypothenuse c subtends a right angle, of which the sine = 1, the R.H. index (or 90°) on S is set to the length of _c_ on A, when under _a_ on A is found _a_° on S. Hence _b_° and _b_ may be determined.

(3.) Given _a_ and _a_°, to find _b_, _c_, and _b_°.

Here _b_° = (90 – _a_°), and the solution is similar to the foregoing.

(4.) Given _a_ and _b_, to find _a_°, _b_°, and _c_.

To find _a_°, we have tan. _a_° = _a_/_b_, which in the above example will be (4·5)/(7·8) = 0·577. Therefore, placing the slide so that the indices of T coincide with those of D, we read opposite 0·577 on D the value of _a_° = 30°. The hypothenuse _c_ is readily obtained from _c_ = _a_/(sin _a_°).

THE SOLUTION OF OBLIQUE-ANGLED TRIANGLES.

Using the same letters as before to designate the three sides and the subtending angles of oblique-angled triangles, we have the following cases:—

(1.) Given one side and two angles, as _a_, _a_°, and _b_°, to find _b_, _c_, and _c_°.

In the first place, _c_° = 180° – (_a_° + _b_°); also we note that, as the sides are proportional to the sines of the opposite angles, _b_ = (_a_ sine _b_°)/(sine _a_°) and _c_ = (_a_ sine _c_°)/(sine _a_°).

Taking as an example, _a_ = 45, _a_° = 57°, and _b_° = 63°, we have _c_° = 180 – (57 + 63) = 60°. To find _b_ and _c_, set _a_° on S to _a_ on A, and read off on A above 63° and 60° the values of _b_ (= 47·8) and _c_ (= 46·4) respectively.

(2.) Given _a_, _b_, and _a_°, to find _b_°, _c_°, and _c_.

In this case the angle _a_° on S is placed under the length of side _a_ on A and under _b_ on A is found the angle _b_° on S. The angle _c_° = 180 – (_a_° + _b_°), whence the length _c_ can be read off on A over _c_° on S.

(3.) Given the sides and the included angle, to find the other side and the remaining angles.

If, for example, there are given _a_ = 65, _b_ = 42, and the included angle _c_° = 55°, we have (_a_ + _b_) ■ (_a_ – _b_) = tan. (_a_° + _b_°)/(2) ■ tan. (_a_° – _b_°)/(2). Then, since _a_° + _b_° = 180° – 55° = 125°, it follows that (_a_° + _b_°)/(2) = (125°)/(2) = 62° 30′.

By the rule for tangents of angles greater than 45°, we find tan. 62° 30′ = 1·92. Inserting in the above proportion the values thus found, we have 107 ■ 23 = 1·92 ■ tan. (_a_° – _b_°)/(2). From this it is found that the value of the tangent is 0·412, and placing the slide with all indices coinciding, it is seen that this value on D corresponds to an angle of 22° 25′. Therefore, since (_a_° + _b_°)/(2) = 62° 30′, and (_a_° – _b_°)/(2) = 22° 25′, it follows that _a_° = 84° 55′, and _b_° = 40° 5′. Finally, to determine the side _c_, we have _c_ = (_a_ sin _c_°)/(sin _a_°) as before.

PRACTICAL TRIGONOMETRICAL APPLICATIONS.

A few examples illustrative of the application of the methods of determining the functions of angles, etc., described in the preceding section, will now be given.

To find the chord of an arc, having given the included angle and the radius.

With the slide placed in the rule with the C and D scales outward, bring one-half of the given angle on S to the index mark in the back of the rule, and read the chord on B under twice the radius on A.

EX.—Required the chord of an arc of 15°, the radius being 23 in.

Set 7° 30′ on S to the index mark in the back of the rule, and under 46 on A read 6 in., the required length of chord on B.

To find the area of a triangle, given two sides and the included angle.

Set the angle on S to the index mark on the back of the rule, and bring cursor to 2 on B. Then bring the length of one side on B to cursor, cursor to 1 on B, the length of the other side on B to cursor, and read area on B under index of A.

EX.—The sides of a triangle are 5 and 6 ft. in length respectively, and they include an angle of 20°. Find the area.

Set 20 on S to index mark, bring cursor to 2 on B, 5 on B to cursor, cursor to 1 on B, 6 on B to cursor, and under 1 on A read the area = 5·13 sq. ft. on B.

To find the number of degrees in a gradient, given the rise per cent.

Place the slide with the indices of T coincident with those of D, and over the rate per cent. on D read number of degrees in the slope on T.

As the arrangement of rule we have chiefly considered has only a single T scale, it will be seen that only solutions of the above problem involving slopes between 10 and 100 per cent. can be directly read off. For smaller angles, one of the formulæ for the determination of the tangents of submultiple angles must be used.

In rules having a double T scale (which is used with the A scale) the value in degrees of any slope from 1 to 100 per cent. can be directly read off on A.

To find the number of degrees, when the gradient is expressed as 1 in _x_.

Place the index of T to _x_ on D, and over index of D read the required angle in degrees on T.

EX.—Find the number of degrees in a gradient of 1 in 3·8.

Set 1 on T to 3·8 on D, and over R.H. index of D read 14° 45′ on T.

Given the lap, the lead and the travel of an engine slide valve, to find the angle of advance.

Set (lap + lead) on B to half the travel of the valve on A, and read the angle of advance on S at the index mark on the back of the rule.

EX.—Valve travel 4½in., lap 1 in., lead ■/■■in. Find angle of advance.

Set 1■/■■ = 1·312 on B to 2·25 on A, and read 35° 40′ on S opposite the index on the back of the rule.

Given the angular advance θ, the lap and the travel of a slide valve, to find the cut-off in percentage of the stroke.

Place the lap on B to half the travel of valve on A, and read on S the angle (the supplement of the _angle of the eccentric_) found opposite the index in the back of the rule. To this angle, add the angle of advance and deduct the sum from 180°, thus obtaining the _angle of the crank_ at the point of cut-off. To the cosine of the supplement of this angle, add 1 and multiply the result by 50, obtaining the percentage of stroke completed when cut-off occurs.

EX.—Given the angular advance = 35° 40′, the valve travel = 4½in., and the lap = 1 in., find the angle of the crank at cut-off and the admission period expressed as a percentage of the stroke.

Set 1 on B to 2·25 on A, and read off on S opposite the index, the supplement of the angle of the eccentric = 26° 20′. Then 180° – (35° 40′ + 26° 20′) = 118° = the crank angle at the point of cut-off. Further, cos. 118° = cos. 62° = sin (90° – 62°) = sin 28°, and placing 28° on S to the back index, the cosine, read on B under R.H. index of A, is found to be 0·469. Adding 1 and placing the L.H. index of C to the result, 1·469, on D, we read off under 50 on C, the required period of admission = 73·4 per cent. on D.

The trigonometrical scales are useful for evaluating certain formulæ. Thus in the following expressions, if we find the angle _a_ such that sin. _a_ = _k_, we can write:—

(_k_)/(√1 – _k^2_) = tan. _a_; (√1 – _k^2_)/(_k_) = cot. _a_; √(1 – _k^2_) = cos. _a_; etc.

In the first expression, take _k_ = 0·298. Place the slide with the sine scale outward and with its indices agreeing with the indices of the rule. Set the cursor to 0·298 on the (R.H.) scale of A, and read 17° 20′ on the sine scale as the angle required. Then under 17° 20′ on the tangent scale, read 0·312 on D as the result.

SLIDE RULES WITH LOG.-LOG. SCALES.

For occasional requirements, the method described on page 45 of determining powers and roots other than the square and cube, is quite satisfactory. When, however, a number of such calculations are to be made, the process may be simplified considerably by the use of what are known as _log.-log._, _logo-log._, or _logometric_ scales, in conjunction with the ordinary scales of the rule. The principle involved will be understood from a consideration of those rules for logarithmic computation (page 8) which refer to powers and roots. From these it is seen that while for the multiplication and division of numbers we _add_ their logarithms, for involution and evolution we require to _multiply_ or _divide_ the logarithms of the numbers by the exponent of the power or root as the case may be. Thus to find 3^{2.3}, we have (log. 3) × 2·3 = log. _x_, and by the ordinary method described on page 45 we should determine log. 3 by the aid of the scale L on the back of the slide, multiply this by 2·3 by using the C and D scales in the usual manner, transfer the result to scale L, and read the value of _x_ on D under 1 on C. By the simpler method, first proposed by Dr. P. M. Roget,[8] the multiplication of log. 3 by 2·3 is effected in the same way as with any two ordinary factors—_i.e._, by adding their logarithms and finding the number corresponding to the resulting logarithm. In this case we have log. (log. 3) + log. 2·3 = log. (log. _x_). The first of the three terms is obviously the _logarithm of the logarithm_ of 3, the second is the simple logarithm of 2·3, and the third the _logarithm of the logarithm of_ the answer. Hence, if we have a scale so graduated that the distances from the point of origin represent the logarithms of the logarithms (the log.-logs.) of the numbers engraved upon it, then by using this in conjunction with the ordinary scale of logarithms, we can effect the required multiplication in a manner which is both expeditious

and convenient. Slightly varying arrangements of the log.-log. scale, sometimes referred to as the “P line,” have been introduced from time to time, but latterly the increasing use of exponential formulæ in thermodynamic, electrical, and physical calculations has led to a revival of interest in Dr. Roget’s invention, and various arrangements of rules with log.-log. scales are now available.

The Davis Log.-Log. Rule.—In the rule introduced by Messrs. John Davis & Son Limited, Derby, the log.-log. scales are placed upon a separate slide—a plan which has the advantage of leaving the rule intact for all ordinary purposes, while providing a length of 40 in. for the log.-log. scales.

In the 10 in. Davis rule one face of the slide, marked E, has two log.-log. scales for numbers greater than unity, the lower extending from 1·07 to 2, and the upper continuing the graduations from 2 to 1000. On the reverse face of the slide, marked -E, are two log.-log. scales for numbers less than unity, the upper extending from 0·001 to 0·5, and the lower continuing the graduations from 0·5 to 0·933. Both sets of scales are used in conjunction _with the lower or D scale of the rule_, which is to be primarily regarded as running from 1 to 10, and constitutes a scale of exponents. In the 20 in. rule the log.-log. scales are more extensive, and are used in conjunction with the upper or A scale of the rule (1 to 100); in what follows, however, the 10 in. rule is more particularly referred to.

It has been explained that on the log.-log. scale the distance of any numbered graduation from the point of origin represents the log.-log. of the number. The point of origin will obviously be that graduation whose log.-log. = 0. This is seen to be 10, since log. (log. 10) = log. 1 = 0. Hence, confining attention to the E scale, to locate the graduation 20, we have log. (log. 20) = log. 1·301 = 0·11397, so that if the scale D is 25 cm. long, the distance between 10 and 20 on the corresponding log.-log. scale would be 113·97 ÷ 4 = 28·49 mm. For numbers less than 10 the resulting log.-logs. will be negative, and the distances will be spaced off from the point of origin in a negative direction—_i.e._, from right to left. Thus, to locate the graduation 5, we have

log. (log. 5) = log. 0·699 = ■1·844; _i.e._, –1 + 0·844 or –0·156;

so that the graduation marked 5 would be placed 156 ÷ 4 = 39 mm. distant from 10 in a _negative_ direction, and proceeding in a similar manner, the scale may be extended in either direction. In the -E scale, the notation runs in the reverse direction to that of the E scale, but in all other respects it is precisely analogous, the distance from the point of origin (0·1 in this case) to any graduation _x_ representing log. [-log. _x_.]. It follows that of the similarly situated graduations on the two scales, those on the -E scale are the _reciprocals_ of those on the E scale. This may be readily verified by setting, say, 10 on E to (R.H.) 1 on D, when turning to the back of the rule we find 0·1 on -E agreeing with the index mark in the aperture at the right-hand extremity of the rule.

In using the log.-log. scales it is important to observe (1) that the values engraved on the scale are definite and unalterable (_e.g._, 1·2 can only be read as 1·2 and not as 120, 0·0012, etc., as with the ordinary scales); (2) that the upper portion of each scale should be regarded as forming a prolongation to the right of the lower portion; and (3) that immediately above any value on the lower portion of the scale is found the 10th power of that value on the upper portion of the scale. Keeping these points in view, if we set 1·1 on E to 1 on D we find over 2 on D the value of 1·1^2 = 1·21 on E. Similarly, over 3 we find 1·1^3 = 1·331, and so on. Then, reading across the slide, we have, over 2, the value of 1·1^{2 × 10} = 1·1^{20} = 6·73, and over 3 we have 1·1^{3 × 10} = 1·1^{30} = 17·4. Hence the rule:—_To find the value of x^n, set x on E to 1 on D, and over n on D read x^n on E._

With the slide set as above, the 8th, 9th, etc., powers of 1·1 cannot be read off; but it is seen that, according to (2) in the foregoing, the missing portion of the E scale is that part of the upper scale (2 to about 2·6) which is outside the rule to the left. Hence placing 1·1 to 10 on D, the 8th, 9th, etc., powers of 1·1 will be read off _on the upper part_ of the E scale. In general, then,

If _x_ on the _lower_ line is set to 1 on D, then _x^n_ is read directly on that line and _x_^{10_n_} on the upper line.

If _x_ on the _upper_ line is set to 1 on D, then _x^n_ is read directly on that line and _x_^{_■/■■_} on the lower line.

If _x_ on the _lower_ line is set to 10 on D, then _x_^{_■/■■_} is read directly on that line and _x^n_ on the upper line.

If _x_ on the _upper_ line is set to 10 on D, then _x_^{_■/■■_} is read directly on that line and _x_^{_■/■■■_} on the lower line.

These rules are conveniently exhibited in the accompanying diagram (Fig. 14). They are equally applicable to both the E and -E scales of the 10 in. rule, and include practically all the instruction required for determining the _n_th power or the _n_th root of a number. They do not apply directly to the 20 in. rule, however, for here the relation of the lower and upper scales will be _x^n_ and _x_^{100_n_}.

EX.—Find 1·167^{2·56}.

Set 1·167 on E to 1 on D, and over 2·56 on D read 1·485 on E.

EX.—Find 4·6^{1·61}.

Set 4·6 on upper E scale to 1 on D, and over 1·61 on D read 11·7 (11·67) on E.

EX.—Find 1·4^{0·27} and 1·4^{2·7}.

Set 1·4 on E to 10 on D, and over 2·7 on D read 1·095 = 1·4^{0·27} on lower E scale and 2·48 = 1·4^{2·7} on upper E scale.

[Illustration: FIG. 14.]

EX.—Find 46^{0·0184} and 46^{0·184}.

Set 46 on upper E scale to 10 on D, and over 1·84 on D read 1·073 on lower E scale and 2·022 (2·0228) on upper E scale.

EX.—Find 0·074^{1·15}.

Using the -E scale, set 0·074 to 1 on D, and over 1·15 on D read 0·05 on -E.

The method of determining the root of a number will be obvious from the preceding examples.

EX.—Find ^{1.4}√(17) and ^{14}√(17).

Set 17 on E to 1·4 on D, and over 1 on D read 7·56 on upper E scale and 1·224 on lower E scale.

EX.—Find ^{0·031}√(0·914).

Set 0·914 on -E to 3·1 on D, and over 10 on D read 0·055 on upper -E scale.

When the exponent _n_ is fractional, it is often possible to obtain the result directly with one setting of the slide. Thus to determine 1·135^{¹■/■■} by the first method we find ¹■/■■ = 1·0625, and placing 1·135 on E to 1 on D, read 1·144 on E over 1·0625 on D. By the direct method we place 1·135 on the E scale on 1·6 on D, and over 1·7 on D read 1·144 on E. It will be seen that since the scale D is assumed to run from 1 to 10 we are unable to read 16 and 17 on this scale; but it is obvious that the _ratios_ (1·7)/(1·6) and (17)/(16) are identical, and it is with the ratio only that we are, in effect, concerned.

Since an expression of the form _x_^{-_n_} = (1)/(_x^n_) or ((1)/(_x_))^{_n_}, the required value may be obtained by first determining the reciprocal of _x_ and proceeding as before. By using both the direct and reciprocal log.-log. scales (E and -E) in conjunction however, the required value can be read directly from the rule, and the preliminary calculation entirely avoided. In the Davis form of rule, the result can be read on the -E scale, used in conjunction with the D scale of the rule, _x_ on E being set to the index mark in the aperture in the back of the rule.

EX.—Find the value of 1·195^{–1·65}.

Set 1·195 on E to the index in the left aperture in the back of the rule, and over 1·65 on D read 0·745 on the -E scale.

It may be noted in passing that the log.-log. scale affords a simple means for determining the logarithm or anti-logarithm of a number to any base. For this purpose it is necessary to set the base of the given system on E to 1 on D, when _under_ any number on E will be found its logarithm on D. Thus, for common logs., we set the base 10 on E to 1 on D, and under 100 we find 2, the required log. Similarly we read log. 20 = 1·301; log. 55 = 1·74; log. 550 = 2·74, etc. Reading reversely, over 1·38 on D we find its antilog. 24 on E; also antilog. 1·58 = 38; antilog. 1·19 = 15·5, etc.

For logs. of numbers under 10 we set the base 10 to 10 on D; hence the readings on D will be read as one-tenth their apparent value. Thus log. 3 = 0·477; log. 5·25 = 0·72; antilog. 0·415 = 2·6; antilog. 0·525 = 3.·35, etc.

The logs. of the numbers on the lower half of the E scale will also be found on the D scale; but a consideration of Fig. 14 will show that this will be read as _one-tenth_ its face value if the base is set to 1 on D, and as _one-hundredth_ if the base is set to 10.

For natural, hyperbolic, or Napierian logarithms, the base is 2·718. A special line marked ε or _e_ serves to locate the exact position of this value on the E scale, and placing this to 1 on D we read log._{_e_} 4·35 = 1·47; log._{_e_} 7·4 = 2·0; antilog._{_e_} × 2·89 = 18, etc. The other parts of the scale are read as already described for common logs. Calculations involving powers of _e_ are frequently met with, and these are facilitated by using the special graduation line referred to, as will be readily understood.

If it is required to determine the power or root of a number which does not appear on either of the log.-log. scales, we may break up the number into factors. Usually it is convenient to make one of the factors a power of 10.

EX.—3950^{1·97} = 3·95^{1·97} × 10^{3 × 1·97} = 3·95^{1·97} × 10^{5·91}.

Then 3·95^{1·97} = 15, and 10^{5·91} (or antilog.) 5·91 = 812,000. Hence, 15 × 812,000 = 12,180,000 is the result sought.

Numbers which are to be found in the higher part of the log.-log. scale may often be factorised in this way, and greater accuracy obtained than by direct reading.

The form of log.-log. rule which has been mainly dealt with in the foregoing gives a scale of comparatively long range, and the only objection to the arrangement adopted is the use of a separate slide.

The Jackson-Davis Double Slide Rule.—In this instrument a pair of aluminium clips enable the log.-log. slide to be temporarily attached to the lower edge of the ordinary rule, and used, by means of a special cursor, in conjunction with the C scale of the ordinary slide. In this way both the log.-log. and ordinary scales are available without the trouble of replacing one slide by the other. Since the scale of exponents is now on the slide, the value of _x^n_ will be obtained by setting 1 on C to _x_ on E and reading the result on E under _n_ on C.

By using a pair of log.-log. slides, one in the rule and one clamped to the edge by the clips, we have an arrangement which is very useful in deducing empirical formulæ of the type _y_ = _x^n_.

The Yokota Slide Rule.—In this instrument the log.-log. scales are placed on the face of the rule, each set comprising three lines. These, for numbers greater than 1, are found above the A scale while the three reciprocal log.-log. lines are below the D scale. Both sets are used in conjunction with the C scale on the slide. Other features of this rule are:—The ordinary scales are 10 in. long instead of 25 cm. as hitherto usual; hence the logarithms of numbers can be read on the ordinary scale of inches on the edge of the rule. There is a scale of cubes in the centre of the slide and on the back of the slide there is a scale of secants in addition to the sine and tangent scales.

[Illustration: FIG. 15.]

The Faber Log.-log. Rule.—In this instrument shown in Fig. 15, the two log.-log. scales are placed on the face of the rule. One section, extending from 1·1 to 2·9, is placed above the A scale, and the other section, extending from 2·9 to 100,000, is placed below the D scale. These scales are used in conjunction with the C scale of the slide in the manner previously described. The width of the rule is increased slightly, but the arrangement is more convenient than that formerly employed, wherein the log.-log. scales were placed on the bevelled edge of the rule and read by a tongue projecting from the cursor.

[Illustration: FIG. 16.]

Another novel feature of this rule is the provision of two special scales at the bottom of the groove, to which a bevelled metal index or marker on the left end of the slide can be set. The upper of these scales is for determining the efficiency of dynamos and electric motors; the lower for determining the loss of potential in an electric circuit.

The Perry Log.-log. Rule.—In this rule, introduced by Messrs. A. G. Thornton, Limited, Manchester, the log.-log. scales are arranged as in Fig. 16, the E scale, running from 1·1 to 10,000, being placed above the A scale of the rule, and the -E or E^{–1} scale running from 0·93 to 0·0001, below the D scale of the rule. These scales are read in conjunction with the B scales on the slide by the aid of the cursor.

The following tabular statement embodies all the instructions required for using this form of log.-log. slide rule:—

When _x_ is greater than 1.

_x^n_ Set 1 on B to _x_ on E; over _n_ on B read _x^n_ on E _x_^{-_n_} Set 1 on B to _x_ on E; under _n_ on B read _x_^{-_n_} on E^{–1} _x_^{_■/■_} Set _n_ on B to _x_ on E; over 1 on B read _x_^{_■/■_} on E _x_^{_■■/■_} Set _n_ on B to _x_ on E; under 1 on B read _x_^{_■■/■_} on E^{–1}

When _x_ is less than 1.

_x^n_ Set 1 on B to _x_ on E^{–1}; under _n_ on B read _x^n_ on E^{–1} _x_^{-_n_} Set 1 on B to _x_ on E^{–1}; over _n_ on B read _x_^{-_n_} on E _x_^{_■/■_} Set _n_ on B to _x_ on E^{–1}; under 1 on B read _x_^{_■/■_} on E^{–1} _x_^{_■■/■_} Set _n_ on B to _x_ on E^{–1}; over 1 on B read _x_^{_■■/■_} on E

If 10 on B is used in place of 1 on B, read _x_^{_■/■■_} in place of _x^n_ on E, and _x_^{-_■/■■_} in place of _x_^{-_n_} on E^{–1}. If 100 on B is used, these readings are to be taken as _x_^{_■/■■■_} and _x_^{-_■/■■■_} respectively.

In rules with no -E scale the value of _x_^{-_n_} is obtained by the usual rules for reciprocals. We may either determine _x^n_ and find its reciprocal or, first find the reciprocal of _x_ and raise it to the _n_th power. The first method should be followed when the number _x_ is found on the E scale.

EX.—3·45^{–1·82} = 0·105.

Set 1 on C to 3·45 on E, and under 1·82 on C read 9·51 on C. Then set 1 on B to 9·5 on A, and under index of A read 0·105 on B.

When _x_ is less than 1 the second method is more suitable.

EX.—0·23^{–1·77} = ((1)/(0·23))^{1·77} = 4·35^{1·77} = 13·5

Set 1 on B to 0·23 on A, and under index of A read (1)/(0·23) = 4·35 on B.

Set 1 on C to 4·35 on E, and under 1·77 on C read 13·5 on E.

As with the Davis rule, the exponent scale C will be read as ■th its face value if its R.H. index (10) is used in place of 1.

SPECIAL TYPES OF SLIDE RULES.

In addition, to the new forms of log.-log. slide rules previously described, several other arrangements have been recently introduced, notably a series by Mr. A. Nestler, of Lahr (London: A. Fastlinger, Snow Hill). These comprise the “Rietz,” the “Precision,” the “Universal,” and the “Fix” slide rules.

THE RIETZ RULE.—In this rule the usual scales A, B, C, and D, are provided, while at the upper edge is a scale, which, being three times the range of the D scale, enables cubes and cube roots to be directly evaluated and also _n_^{⅓■} and _n_^■.

A scale at the lower edge of the rule gives the mantissa of the logarithms of the numbers on D.

THE PRECISION SLIDE RULE.—In this rule the scales are so arranged that the accuracy of a 20 in. rule is obtainable in a length of 10 in. This is effected by dividing a 20 in. (50 cm.) scale length into two parts and placing these on the working edges of the rule and slide. On the upper and lower margins of the face of the rule are the two parts of what corresponds to the A scale in the ordinary rule; while in the centre of the slide is the scale of logarithms which, used in conjunction with the 50 cm. scales on the slide, is virtually twice the length of that ordinarily obtainable in a 10 in. rule. The same remark applies to the trigonometrical scales on the under face of the slide. Both the sine and tangent scales are in two adjacent lengths, while on the edge of the stock of the rule, below the cursor groove, is a scale of sines of small angles from 1° 49′ to 5° 44′. This is referred to the 50 cm. scales by an index projection on the cursor.

If C and C′ are the two parts of the scale on the slide and D and D′ the corresponding scales on the rule, it is clear that in multiplying two factors 1 on C can only be set directly to the upper scale D; while 10 on C′ can only be set directly to the lower scale D′. Hence if the first factor is greater than about 3·2, the cursor must be used to bring 1 on C to the first factor on D′. Similarly, in division, numerators and denominators which occur on C and D′ or on C′ and D cannot be placed in direct coincidence but must be set by the aid of the cursor.

Any uncertainty in reading the result can be avoided by observing the following rule: _If in setting the index_ (1 _or_ 10) _in multiplication, or in setting the numerator to the denominator in division, it is necessary to cross the slide, then it will also be necessary to cross the slide to read the product or quotient._

THE UNIVERSAL SLIDE RULE.—In this instrument the stock carries two similar scales running from 1 to 10, to which the slide can be set. Above the upper one is the logarithm scale and under the lower one the scale of squares 1 to 100. On the edge of the stock of the rule, under the cursor groove, is a scale running from 1 to 1000. An index projecting from the cursor enables this scale to be used with the scales on the face of the rule, giving cubes, cube roots, etc.

On the slide, the lower scale is an ordinary scale, 1 to 10. The centre scale is the first part of a scale giving the values of sin _n_ cos _n_, this scale being continued along the upper edge of the slide (marked “sin-cos”) up to the graduation 50. On the remainder of this line is a scale running from right to left (0 to 50) and giving the value of cos^2_n_. In surveying, these scales greatly facilitate the calculations for the horizontal distance between the observer’s station and any point, and the difference in height of these two points.

On the back of the slide are scales for the sines and tangents of angles. The values of the sines and tangents of angles from 34′ to 5° 44′ differ little from one another, and the one centre scale suffices for both functions of these small angles.

THE FIX SLIDE RULE.—This is a standard rule in all respects, except that the A scale is displaced by a distance (π)/(4) so that over 1 on D is found 0·7854 on A. This enables calculations relating to the area and cubic contents of cylinders to be determined very readily.

THE BEGHIN SLIDE RULE.—We have seen that a disadvantage attending the use of the ordinary C and D scales, is that it is occasionally necessary to traverse the slide through its own length in order to change the indices or to bring other parts of the slide into a readable position with regard to the stock. To obviate this disadvantage, Tserepachinsky devised an ingenious arrangement which has since been used in various rules, notably in the Beghin slide rule made by Messrs. Tavernier-Gravêt of Paris. In this rule the C and D scales are used as in the standard rule, but in place of the A and B scales, we have another pair of C and D scales, displaced by one-half the length of the rule. The lower pair of scales may therefore be regarded as running from 10^{_n_} to 10^{_n_ + 1}, and the upper pair as running from √(10) × 10^{_n_} to √(10) × 10^{_n_ + 1}. With this arrangement, _without moving the slide more than half its length_, to the left or right, it is always possible to compare _all values between_ 1 _and_ 10 _on the two scales_. This is a great advantage especially in continuous working.

Another commendable feature of the Beghin rule is the presence of a reversed C scale in the centre of the slide, thus enabling such calculations as _a_ × _b_ × _c_ to be made with one setting of the slide. On the back of the slide are three scales, the lowest of which, used with the D scale, is a scale of squares (corresponding to the ordinary B scale), while on the upper edge is a scale of sines from 5° 44′ to 90°, and in the centre, a scale of tangents from 5° 43′ to 45°. On the square edge of the stock, under the cursor groove, is the logarithm scale, while on the same edge, above the cursor groove, are a series of gauge points. All these values are referred to the face scales by index marks on the cursor.

THE ANDERSON SLIDE RULE.—The principle of dividing a long scale into sections as in the Precision rule, has been extended in the Anderson slide rule made by Messrs. Casella & Co., London, and shown in Fig. 17. In this the slide carries a scale in four sections, used in conjunction with an exactly similar set of scale-lines in the upper part of the stock. On the lower part of the stock is a scale in eight sections giving the square roots of the upper values. In order to set the index of the slide to values in the stock, two indices of transparent celluloid are fixed to the slide extending over the face of the rule as shown in the illustration. As each scale section is 30 cm. in length, the upper lines correspond to a single scale of nearly 4 ft., and the lower set to one of nearly 8 ft. in length, giving a correspondingly large increase in the number of subdivisions of these scales, and consequently much greater accuracy.

In order to decide upon which line a result is to be found, sets of “line numbers” are marked at each end of the rule and slide and also on the metal frame of the cursor. In multiplication, the line number of the product is the sum of the line numbers of the factors if the left index is used, or 1 more than this sum if the right index is used. The illustration shows the multiplication of 2 by 4. The left index is set to 2 (line number, 1), and the cursor set to 4 on the slide (line number, 2); hence, as the left index is used, the result is found on line No. 3. Similar rules are readily established for division. The column of line numbers headed 0 is used for units, that headed 4 for tens, and so on; one column is given for tenths, headed –4. The square root scale bears similar line numbers, so that the square root of any value on the upper scales is found on the correspondingly figured line below.

[Illustration: FIG. 17.]

THE MULTIPLEX SLIDE RULE differs from the ordinary form of rule in the arrangement of the B scale. The right-hand section of this scale runs from left to right as ordinarily arranged, but the left-hand section runs in the reverse direction, and so furnishes a reciprocal scale. At the bottom of the groove, under the slide, there is a scale running from 1 to 1000, which is used in conjunction with the D scale, readings being referred thereto by a metal index on the end of the slide. By this means cubes, cube roots, etc., can be read off directly. Messrs. Eugene Dietzgen & Co., New York, are the makers.

THE “LONG” SLIDE RULE has one scale in two sections along the upper and lower parts of the stock, as in the “Precision” rule. The scale on the slide is similarly divided, but the graduations run in the reverse direction, corresponding to an inverted slide. Hence the rules for multiplication and division are the reverse of those usually followed (page 30). On the back of the slide is a single scale 1–10, and a scale 1–1000, giving cubes of this single scale. By using the first in conjunction with the scales on the stock, squares may be read, while in conjunction with the cube scale, various expressions involving squares, cubes and their roots may be evaluated.

HALL’S NAUTICAL SLIDE RULE consists of two slides fitting in grooves in the stock, and provided with eight scales, two on each slide, and one on each edge of each groove. While fulfilling the purposes of an ordinary slide rule, it is of especial service to the practical navigator in connection with such problems as the “reduction of an ex-meridian sight” and the “correction of chronometer sights for error in latitude.” The rule, which has many other applications of a similar character, is made by Mr. J. H. Steward, Strand, London.

LONG-SCALE SLIDE RULES

It has been shown that the degree of accuracy attainable in slide-rule calculations depends upon the length of scale employed. Considerations of general convenience, however, render simple straight-scale rules of more than 20 in. in length inadmissible, so that inventors of long-scale slide rules, in order to obtain a high degree of precision, combined with convenience in operation, have been compelled to modify the arrangement of scales usually employed. The principal methods adopted may be classed under three varieties: (1) The use of a long scale in sectional lengths, as in Hannyngton’s Extended Slide Rule and Thacher’s Calculating Instrument; (2) the employment of a long scale laid in spiral form upon a disc, as in Fearnley’s Universal Calculator and Schuerman’s Calculating Instrument; and (3) the adoption of a long scale wound helically upon a cylinder, of which Fuller’s and the “R.H.S.” Calculating Rules are examples.

FULLER’S CALCULATING RULE.—This instrument, which is shown in Fig. 18, consists of a cylinder _d_ capable of being moved up and down and around the cylindrical stock _f_, which is held by the handle. The logarithmic scale-line is arranged in the form of a helix upon the surface of the cylinder _d_, and as it is equivalent to a straight scale of 500 inches, or 41 ft. 8 in., it is possible to obtain four, and frequently five, figures in a result.

Upon reference to the figure it will be seen that three indices are employed. Of these, that lettered _b_ is fixed to the handle; while two others, _c_ and _a_ (whose distance apart is equal to the axial length of the complete helix), are fixed to the innermost cylinder _g_. This latter cylinder slides telescopically in the stock _f_, enabling the indices to be placed in any required position relatively to _d_. Two other scales are provided, one (_m_) at the upper end of the cylinder _d_, and the other (_n_) on the movable index.

[Illustration: FIG. 18.]

In using the instrument a given number on _d_ is set to the fixed index _b_, and either _a_ or _c_ is brought to another number on the scale. This establishes a ratio, and if the cylinder is now moved so as to bring any number to _b_, the fourth term of the proportion will be found under _a_ or _c_. Of course, in multiplication, one factor is brought to _b_, and _a_ or _c_ brought to 100. The other factor is then brought to _a_ or _c_, and the result read off under _b_. Problems involving continuous multiplication, or combined multiplication and division, are very readily dealt with. Thus, calling the fixed index F, the upper movable index A, and the lower movable index B, we have for _a_ × _b_ × _c_:—Bring _a_ to F; A to 100; _b_ to A or B; A to 100; _c_ to A or B and read the product at F.

The maximum number of figures in a product is the sum of the number of figures in the factors and this results when all the factors except the first have to be brought to B. Each time a factor is brought to A, 1 is to be deducted from that sum.

For division, as _a_/(_m_ × _n_), bring _a_ to F; A or B to _m_; 100 to A; A or B to _a_; 100 to A and read the quotient at F.

[Illustration: FIG. 19.]

The maximum number of figures in the quotient is the difference between the sum of the number of figures in the numerator factors and those of the denominator factors, _plus_ 1 for each factor of the denominator and this results when A has to be set to all the factors of the denominator and all the factors of the numerator except the first brought to B. Each time B is set to a denominator factor or a numerator factor is brought to A, 1 is to be deducted.

Logarithms of numbers are obtained by using the scales _m_ and _n_ and hence powers and roots of any magnitude may be obtained by the procedure already fully explained. The instrument illustrated is made by Messrs. W. F. Stanley & Co., Limited, London.

THE “R.H.S.” CALCULATOR.—In this calculator, designed by Prof. R. H. Smith, the scale-line, which is 50 in. long, is also arranged in a spiral form (Fig. 19), but in this case it is wrapped around the central portion of a tube which is about ¾in. in diameter and 9½in. long. A slotted holder, capable of sliding upon the plain portions of this tube, is provided with four horns, these being formed at the ends of the two wide openings through which the scale is read. An outer ring carrying two horns completes the arrangement.

One of the horns of the holder being placed in agreement with the first factor, and one of the horns of the ring with the second factor, the holder is moved until the third factor falls under the same horn of the ring, when the resulting fourth term will be found under the same (right or left) horn of the holder, at either end of the slot. In multiplication, 100 or 1000 is taken for the second factor in the above proportion, as already explained in connection with Fuller’s rule; indeed, generally, the mode of operation is essentially similar to that followed with the former instrument.

The scale shown on one edge of the opening in the holder, together with the circular scale at the top of the spiral, enables the mantissæ of logarithms of numbers to be obtained, and thus problems involving powers and roots may be dealt with quite readily. This instrument is supplied by Mr. J. H. Steward, London.

THACHER’S CALCULATING INSTRUMENT, shown in Fig. 20, consists of a cylinder 4 in. in diameter and 18 in. long, which can be given both a rotary and a longitudinal movement within an open framework composed of twenty triangular bars. These bars are connected to rings at their ends, which can be rotated in standards fixed to the baseboard. The scale on the cylinder consists of forty sectional lengths, but of each scale-line that part which appears on the right-hand half of the cylinder is repeated on the left-hand half, one line in advance. Hence each half of the cylinder virtually contains two complete scales following round in regular order. On the lower lines of the triangular bars are scales exactly corresponding to those on the cylinder, while upon the upper lines of the bars and not in contact with the slide is a scale of square roots.

[Illustration: FIG. 20.]

By rotating the slide any line on it may be brought opposite any line in frame and by a longitudinal movement any graduation on these lines may be brought into agreement. The whole can be rotated in the supporting standards in order to bring any reading into view. As shown in the illustration, a magnifier is provided, this being conveniently mounted on a bar, along which it can be moved as required.

SECTIONAL LENGTH OR GRIDIRON SLIDE RULES.—The idea of breaking up a long scale into sectional lengths is due to Dr. J. D. Everett, who described such a gridiron type of slide rule in 1866. Hannyngton’s Extended Slide Rule is on the same principle. Both instruments have the lower scale repeated. H. Cherry (1880) appears to have been the first to show that such duplication could be avoided by providing two fixed index points in addition to the natural indices of the scale. These additional indices are shown at 10′ and 100′ in Fig. 21, which represents the lower sheet of Cherry’s Calculator on a reduced scale. The upper member of the calculator consists of a transparent sheet ruled with parallel lines, which coincide with the lines of the lower scale when the indices of both are placed in agreement. To multiply one number by another, one of the indices on the upper sheet is placed to one of the factors, and the position of whichever index falls under the transparent sheet is noted on the latter. Bringing the latter point to the other factor, the result is found under whichever index lies on the card. In other arrangements the inventor used transparent scales, the graduations running in a reverse direction to those of the lower scale. In this case, a factor on the upper scale is set to the other factor on the lower, and the result read at the available index.

[Illustration: FIG. 21.]

PROELL'S POCKET CALCULATOR is an application of the last-named principle. It comprises a lower card arranged as Fig. 21, with an upper sheet of transparent celluloid on which is a similar scale running in the reverse direction. For continued multiplication and division, a needle (supplied with the instrument) is used as a substitute for a cursor, to fix the position of the intermediate results. A series of index points on the lower card enable square and cube roots to be extracted very readily. This calculator is supplied by Messrs. John J. Griffin & Sons, Ltd., London.

CIRCULAR CALCULATORS.

Although the 10 in. slide rule is probably the most serviceable form of calculating instrument for general purposes, many prefer the more portable circular calculator, of which many varieties have been introduced during recent years. The advantages of this type are: It is more compact and conveniently carried in the waistcoat pocket. The scales are continuous, so that no traversing of the slide from 1 to 10 is required. The dial can be set quickly to any value; there is no trouble with tight or ill-fitting slides. The disadvantages of most forms are: Many problems involve more operations than a straight rule. The results being read under fingers or pointers, an error due to parallax is introduced, so that the results generally are not so accurate as with a straight rule. The inner scales are short, and therefore are read with less accuracy. Special scale circles are needed for cubes and cube roots. The slide cannot be reversed or inverted.

[Illustration: FIG. 22.]

[Illustration: FIG. 23.]

THE BOUCHER CALCULATOR.—This circular calculator resembles a stem-winding watch, being about 2 in. in diameter and ■/■■in. in thickness. The instrument has two dials, the back one being fixed, while the front one, Fig. 22 (showing the form made by Messrs. W. F. Stanley, London), turns upon the large centre arbor shown. This movement is effected by turning the milled head of the stem-winder. The small centre axis, which is turned by rotating the milled head at the side of the case, carries two fine needle pointers, one moving over each dial, and so fixed on the axis that one pointer always lies evenly over the other. A fine index or pointer fixed to the case in line with the axis of the winding stem, extends over the four scales of the movable dial as shown. Of these scales, the second from the outer is the ordinary logarithmic scale, which in this instrument corresponds to a straight scale of about 4¾in. in length. The two inner circles give the square roots of the numbers on the primary logarithmic scale, the smaller circle containing the square roots of values between 1 and 3·162 (= √(10)), while the other section corresponds to values between 3·162 and 10. The outer circle is a scale of logarithms of sines of angles, the corresponding sines of which can be read off on the ordinary scale.

On the fixed or back dial there are also four scales, these being arranged as in Fig. 23. The outer of these is a scale of equal parts, while the three inner scales are separate sections of a scale giving the cube roots of the numbers taken on the ordinary logarithmic scale and referred thereto by means of the pointers. In dividing this cube-root scale into sections, the same method is adopted as in the case of the square-root scale. Thus, the smallest circle contains the cube roots of numbers between 1 and 10, and is therefore graduated from 1 to 2·154; the second circle contains the cube roots of numbers between 10 and 100, being graduated from 2·154 to 4·657; while the third section, in which are found the cube roots of numbers between 100 and 1000, carries the graduations from 4·657 to 10.

What has been said in an earlier section regarding the notation of the slide rule may in general be taken to apply to the scales of the Boucher calculator. The manner of using the instrument is, however, not quite so evident, although from what follows it will be seen that the operative principle—that of variously combining lengths of a logarithmic scale—is essentially similar. In this case, however, it is seen that in place of the straight scale-lengths shown in Fig. 4, we require to add or subtract arc-lengths of the circular scales, while, further, it is evident that in the absence of a fixed scale (corresponding to the stock of the slide rule) these operations cannot be directly performed as in the ordinary form of instrument. However, by the aid of the fixed index and the movable pointer, we can effect the desired combination of the scale-lengths in the following manner. Assuming it is desired to multiply 2 by 3, the dial is turned in a backward direction until 2 on the ordinary scale lies under the fixed index, after which the movable pointer is set to 1 on the scale. As now set, it is clear that the arc-length 1–2 is spaced off between the fixed index and the movable pointer, and it now only remains to add to this definite arc-length a further length of 1–3. To do this we turn the dial still further backward until the arc 1–3 has passed under the movable pointer, when the result, 6, is read under the fixed index. A little consideration will show that any other scale length may be added to that included between the fixed and movable pointers, or, in other words, any number on the scale may be multiplied by 2 by bringing the number to the movable pointer and reading the result

under the fixed index. The rule for multiplication is now evident.

Rule for Multiplication.—_Set one factor to the fixed index and bring the pointer to 1 on the scale; set the other factor to the pointer and read the result under the fixed index._

With the explanation just given, the process of division needs little explanation. It is clear that to divide 6 by 3, an arc-length 1–3 is to be taken from a length 1–6. To this end we set 6 to the index (corresponding in effect to passing a length 1–6 to the left of that reference point) and set the pointer to the divisor 3. As now set, the arc 1–6 is included between 1 on the scale and the index, while the arc 1–3 is included between 1 on the scale and the pointer. Obviously if the dial is now turned forward until 1 on the scale agrees with the pointer, an arc 1–3 will have been deducted from the larger arc 1–6, and the remainder, representing the result of this operation, will be read under the index as 2.

Rule for Division.—_Set the dividend to the fixed index, and the pointer to the divisor; turn the dial until 1 on the scale agrees with the pointer, and read the result under the fixed index._

The foregoing method being an inversion of the rule for multiplication, is easily remembered and is generally advised. Another plan is, however, preferable when a series of divisions are to be effected with a constant divisor—_i.e._, when _b_ in (_a_)/(_b_) = _x_ is constant. In this case 1 on the scale is set to the index and the pointer set to _b_; then if any value of a is brought to the pointer, the quotient _x_ will be found under the index.

Combined Multiplication and Division, as (_a_ × _b_ × _c_)/(_m_ × _n_) = _x_, can be readily performed, while cases of continued multiplication evidently come under the same category, since _a_ × _b_ × _c_ = (_a_ × _b_ × _c_)/(1 × 1) = _x_. Such cases as _a_/(_m_ × _n_ × _r_) = _x_ are regarded as (_a_ × 1 × 1 × 1)/(_m_ × _n_ × _r_) = _x_; while (_a_ × _b_ × _c_)/(_m_) = _x_ is similarly modified, taking the form (_a_ × _b_ × _c_)/(_m_ × 1) = _x_. In all cases the expression must be arranged so that there is _one more factor in the numerator_ than _in the denominator_, _1's being introduced as often as required_. The simple operations of multiplication and division involve a similar disposition of factors, since from the rules given it is evident that _m_ × _n_ is actually regarded as (_m_ × _n_)/(1), while (_m_)/(_n_) becomes in effect (_m_ × 1)/(_n_). It is important to note the general applicability of this arrangement-rule, as it will be found of great assistance in solving more complicated expressions.

As with the ordinary form of slide rule, the factors in such an expression as (_a_ × _b_ × _c_)/(_m_ × _n_) = _x_ are taken in the order:—1st factor of numerator; 1st factor of denominator; 2nd factor of numerator; 2nd factor of denominator, and so on; the 1st factor as _a_ being set to the index, and the result _x_ being finally read at the same point of reference.

EX.—(39 × 14·2 × 6·3)/(1·37 × 19) = 134.

Commence by setting 39 to the index, and the pointer to 1·37; bring 14·2 to the pointer; pointer to 19; 6·3 to the pointer, and read the result 134 at the index.

It should be noted that after the first factor is set to the fixed index, the _pointer_ is set to each of the _dividing_ factors as they enter into the calculation, while the _dial_ is moved for each of the _multiplying_ factors. Thus the dial is first moved (setting the first factor to the index), then the pointer, then the dial, and so on.

Number of Digits in the Result.—If rules are preferred to the plan of roughly estimating the result, the general rules given on pages 21 and 25 should be employed for simple cases of multiplication and division. For combined multiplication and division, modify the expression, if necessary, by introducing 1's, as already explained, and subtract the sum of the denominator digits from the sum of numerator digits. Then proceed by the author's rule, as follows:—

Always turn dial to the LEFT; _i.e._, _against the hands of a watch_.

Note dial movements only; ignore those of the pointer.

Each time 1 on dial agrees with or passes fixed index, ADD _1 to the above difference of digits_.

Each time 1 on dial agrees with or passes pointer, DEDUCT _1 from the above difference of digits_.

Treat continued multiplication in the same way, counting the 1's used as denominator digits as one less than the number of multiplied factors.

EX.—(8·6 × 0·73 × 1·02)/(3·5 × 0·23) = 7·95 [7·95473+].

Set 8·6 to index and pointer to 3·5. Bring 0·73 to pointer (noting that 1 on the scale passes the index) and set pointer to 0·23. Set 1·02 to pointer (noting that 1 on the scale passes the pointer) and read under index 7·95. There are 1 + 0 + 1 = 2 numerator digits and 1 + 0 = 1 denominator digit; while 1 is to be added and 1 deducted as per rule. But as the latter cancel, the digits in the result will be 2 – 1 = 1.

When moving the dial to the left will cause 1 on the dial to pass _both_ index and pointer (thus cancelling), the dial may be turned back to make the setting.

It will be understood that when 1 is the _first_ numerator, and 1 on the dial is therefore set to the index, no digit addition will be made for this, as the actual operation of calculating has not been commenced.

In the Stanley-Boucher calculator (Fig. 23) a small centre scale is added, on which a finger indicates automatically the number of digits to be added or deducted; the method of calculating, however, differs from the foregoing. To avoid turning back to 0 at the commencement of each calculation, a circle is ground on the glass face, so that a pencil mark can be made thereon to show the position of the finger when commencing a calculation.

To Find the Square of a Number.— Set the number, on one or other of the square root scales, to the index, and read the required square on the ordinary scale.

To Find the Square Root of a Number.—Set the number to the index, and if there is an _odd_ number of digits in the number, read the root on the inner circle; if an even number, on the second circle.

To Find the Cube of a Number.—Set 1 on the ordinary scale to the index, and the pointer (on the back dial) to the number on one of the three cube-root scales. Then under the pointer read the cube on the ordinary scale.

To Find the Cube Root of a Number.—Set 1 to index, and pointer to number. Then read the cube root under the pointer on one of the three inner circles on the back dial. If the number has

1, 4, 7, 10 or –2, –5, etc., digits, use the inner circle. 2, 5, 8, 11 or –1, –4, etc., „ „ second circle. 3, 6, 9, 12 or –0, –3, etc., „ „ third circle.

For Powers or Roots of Higher Denomination.—Set 1 to index, the pointer to the number on the ordinary scale, and read on the outer circle on the back dial the mantissa of the logarithm. Add the characteristic (see p. 46), multiply by the power or divide by the root, and set the pointer to the mantissa of the result on this outer circle. Under the pointer on the ordinary scale read the number, obtaining the number of figures from the characteristic.

To Find the Sines of Angles.—Set 1 to index, pointer to the angle on the outer circle, and read under the pointer the _natural sine_ on the ordinary scale; also under the pointer on the outer circle of the back dial read the _logarithmic sine_.

THE HALDEN CALCULEX.—After the introduction of the Boucher calculator in 1876, circular instruments, such as the Charpentier calculator, were introduced, in which a disc turned within a fixed ring, so that scales on the faces of both could be set together and ratios established as on the slide rule. Cultriss's Calculating Disc is another instrument on the same principle. The Halden Calculex, of which half-size illustrations are given in Figs. 24 and 25, represents a considerable improvement upon these early instruments. It consists of an outer metal ring carrying a fixed-scale ring, within which is a dial. On each side of this dial are flat milled heads, so that by holding these between the thumb and forefinger the dial can be set quickly and conveniently. The protecting glass discs, which are not fixed in the metal ring but are arranged to turn therein, carry fine cursor lines, and as these are on the side next to the scales a very close setting can be made quite free from the effects of parallax. This construction not only avoids the use of mechanism, with its risk of derangement, but reduces the bulk of the instrument very considerably, the thickness being about ¼in.

On the front face, Fig. 24, the fixed ring carries an outer evenly-divided scale, giving logarithms, and an ordinary scale, 1–10, which works in conjunction with a similar scale on the edge of the dial. The two inner circles give the square roots of values on the main scales as in the Boucher calculator. On the back face, Fig. 25, the ring bears an outer scale, giving sines of angles from 6° to 90° and an ordinary scale, 1–10, as on the front face. The scales on the dial are all reversed in direction (running from right to left), the outer one consisting of an ordinary (but inverse) scale, 1–10, while the three inner circles give the cube roots of values on this inverse scale. As the fine cursor lines extend over all the scales, a variety of calculations can be effected very readily and

accurately.

[Illustration: FIG. 24.]

[Illustration: FIG. 25.]

SPERRY'S POCKET CALCULATOR, made by the Keuffel and Esser Company, New York (Fig. 26), has two rotating dials, each with its own pointer and fixed index. The S dial has an outer scale of equal parts, an ordinary logarithmic scale, and a square-root scale. The L dial has a single logarithmic scale arranged spirally, in three sections, giving a scale length of 12½in. The pointers are turned by the small milled head, which is concentric with the milled thumb-nut by which the two dials are rotated. The gearing is such that both the L dial and its pointer rotate three times as fast as the S dial and pointer. All the usual calculations can be made with the spiral scale, as with the Boucher calculator, and the result read off on one or other of the three scale-sections. Frequently the point at which to read the result is obvious, but otherwise a reference to the single scale on the S dial will show on which of the three spirals the result is to be found.

[Illustration: FIG. 26.]

The K and E Calculator, also made by the Keuffel and Esser Company, is shown in Figs. 27 and 28. It has two dials, of which only one revolves. This, as shown in Fig. 27, has an ordinary logarithmic scale and a scale of squares. There is an index line engraved on the glass of the instrument. The fixed dial has a scale of tangents, a scale of equal parts and a scale of sines, the latter being on a two-turn spiral. The pointers, which move together, are turned by a milled nut and the movable dial by a thumb-nut, as in Sperry's Calculator, Fig. 26.

[Illustration: FIG. 27.]

[Illustration: FIG. 28.]

SLIDE RULES FOR SPECIAL CALCULATIONS.

ENGINE POWER COMPUTER.—A typical example of special slide rules is shown in Fig. 29, which represents, on a scale of about half full size, the author's Power Computer for Steam, Gas, and Oil Engines. This, as will be seen, consists of a stock, on the lower portion of which is a scale of cylinder diameters, while the upper portion carries a scale of horse-powers. In the groove between these scales are two slides, also carrying scales, and capable of sliding in edge contact with the stock and with each other.

This instrument gives directly the brake horse-power of any steam, gas, or oil engine; the indicated horse-power, the dimensions of an engine to develop a given power, and the mechanical efficiency of an engine. The calculation of piston speed, velocity ratios of pulleys and gear wheels, the circumferential speed of pulleys, and the velocity of belts and ropes driven thereby, are among the other principal purposes for which the computer may be employed.

[Illustration: FIG. 29.]

THE SMITH-DAVIS PIECEWORK BALANCE CALCULATOR has two scales, 11 feet long, having a range from 1d. to £20, and marked so that they can be used either for money or time calculations. The scales are placed on the rims of two similar wheels and so arranged that the divided edges come together. The wheels are mounted on a spindle carried at each end in the bearings of a supporting stand. The wheels are pressed together by a spring, and move as one.

To set the scales one to the other, a treadle gear is arranged to take the pressure of the spring so that when the fixed wheel is held by the left hand the free wheel can be rotated by the right hand in either direction. When the amount of the balance has been set to the combined weekly wage the treadle is released locking the two wheels together, when the whole can be turned and the amounts respectively due to each man read off opposite his weekly wage. The Smith-Davis Premium Calculator is on the same principle but the scales are about 4 feet 6 inches long and the wheels spring-controlled. Both instruments are supplied by Messrs. John Davis & Son, Ltd., Derby.

THE BAINES SLIDE RULE.—In this rule, invented by Mr. H. M. Baines, Lahore, four slides carrying scales are arranged to move, each in edge contact with the next. The slides are kept in contact and given the desired relative movement one to the other, by being attached (at the back), to a jointed parallelogram. On this principle which is of general application, the inventor has made a rule for the solution of problems covered by Flamant's formula for the flow of water in cast-iron pipes:—V =

76·28_d_^{■/■}_s_^{■/■}, in which _s_ is the sine of the inclination or loss of head; _d_ the diameter of the pipe in inches and V the velocity in feet per second. The formula Q = AV is also included in the scope of the rule, Q being the discharge in cubic feet per second and A the cross sectional area of the pipe in square inches.

FARMAR'S PROFIT-CALCULATING RULE.—The application of the slide rule to commercial calculations has been often attempted, but the degree of accuracy required necessitates the use of a long scale, and generally this results in a cumbersome instrument. In Farmar's Profit-calculating Rule the money scale is arranged in ten sections, these being mounted in parallel form on a roller which takes the place of the upper scale of an ordinary rule. The roller, which is ¾in. in diameter, is carried in brackets secured to each end of the stock, so that by rotating the roller any section of the money scale can be brought into reading with the scale on the upper edge of the slide and with which the roller is in contact. This scale gives percentages, and enables calculations to be made showing profit on turnover, profit on cost, and discount. The lower scale on the slide, and that on the stock adjacent to it, are similar to the A and B scales of an ordinary rule. The instrument is supplied by Messrs. J. Casartelli & Son, Manchester.

CONSTRUCTIONAL IMPROVEMENTS IN SLIDE RULES.

The attention of instrument makers is now being given to the devising of means for ensuring the smooth and even working of the slide in the stock of the rule. In some cases very good results are obtained by slitting the back of the stock to give more elasticity.

In the rules made by Messrs. John Davis & Son, a metal strip, slightly curved in cross section as shown at A (Fig. 30), runs for the full length of the stock to which it is fastened at intervals. Near each end of the rule, openings about 1 in. long are made in the metal backing through which the scales on the back of the slide can be read. To prevent warping under varying climatic conditions both the stock of the rule and the slide are of composite construction. The base of the stock is of mahogany, while the grooved sides, firmly secured to the base, are of boxwood. Similarly the centre portion of the slide is of mahogany and the tongued sides of boxwood. Celluloid also enters into the construction, a strip of this material being laid along the bottom of the groove in the stock. A fine groove runs along the centre of this strip in order to give elasticity and to allow the sides of the stock to be pressed together slightly to adjust the fitting of the slide. As a further means of adjustment the makers fit metal clips at each end of the rule, so that by tightening two small screws the stock can be closed on the slide when necessary.

[Illustration: FIG. 30.]

[Illustration: FIG. 32.]

[Illustration: FIG. 31.]

In the rule made by the Keuffel and Esser Company of New York, one strip is made adjustable (Fig. 32).

THE ACCURACY OF SLIDE RULE RESULTS.

The degree of accuracy obtainable with the slide rule depends primarily upon the length of the scale employed, but the accuracy of the graduations, the eyesight of the operator, and, in particular, his ability to estimate interpolated values, are all factors which affect the result. Using the lower scales and working carefully the error should not greatly exceed 0·15 per cent. with short calculations. With successive settings, the discrepancy need not necessarily be greater, as the errors may be neutralised; but with rapid working the percentage error may be doubled. However, much depends upon the graduation of the scales. Rules in which one or more of the indices have been thickened to conceal some slight inaccuracy should be avoided. The line on the cursor should be sharp and fine and both slide and cursor should move smoothly or good work cannot be done. Occasionally a little vaseline or clean tallow should be applied to the edges of the slide and cursor.

That the percentage error is constant throughout the scale is seen by setting 1 on C to 1·01 on D, when under 2 is 2·02; under 3, 3·03; under 5, 5·05, etc., the several readings showing a uniform error of 1 per cent.

A method of obtaining a closer reading of a first setting or of a result on D has been suggested to the author by Mr. M. Ainslie, B.Sc. If any graduation, as 4 on C, is set to 3 on D, it is seen that 4 main divisions on C (40–44) are equal in scale length to 3 main divisions on D (30–33). Hence, very approximately, 1 division on C is equal to 0·75 of a division on D, this ratio being shown, of course, on D under 10 on C. Suppose √(4·3) to be required. Setting the cursor to 4·3 on A, it is seen that the root is something more than 2·06. Move the slide until a main division is found on C, which exactly corresponds to the interval between 2 and the cursor line, on D. The division 27–28 just fits, giving a reading under 10 on C, of 74. Hence the root is read as 2·074. For the higher parts

of the scale, the subdivisions, 1–1·1, etc., are used in place of main divisions. The method is probably more interesting than useful, since in most operations the inaccuracies introduced in making settings will impose a limit on the reliable figures of the result.

For the majority of engineering calculations, the slide rule will give an accuracy consistent with the accuracy of the data usually available. For some purposes, however, _logarithmic section paper_ (the use of which the author has advocated for the last twenty years) will be found especially useful, more particularly in calculations involving exponential formulæ.

APPENDIX.

NEW SLIDE RULES—FIFTH ROOTS, ETC.—THE SOLUTION OF ALGEBRAIC EQUATIONS—GAUGE POINTS AND SIGNS ON SLIDE RULES—TABLES AND DATA—SLIDE RULE DATA SLIPS.

THE PICKWORTH SLIDE RULE.—In this rule, made by Mr. A. W. Faber, the novel feature is the provision of a scale of cubes (F) in the stock or body of the rule. From Fig. 33 it will be seen that the scale is fixed on the bevelled side of a slotted recess in the back of the rule. The slide carries an index mark, which is seen through the slot and can be set to any graduation of the scale; in its normal position it agrees with 1 on the scale. The C scale on the face of the rule is divided into three equal parts by two special division lines, marked II. and III., which, together with the initial graduation 1 of the scale, serve for setting or reading off values on the D scale. Similar division lines are marked on the D scale.

[Illustration: FIG. 33.]

In using the rule for cubes or cube roots the slide is drawn to the right, this movement never exceeding one-third of the length of the D scale. With this limited movement, and with a single setting of the slide, the values of ■_■a_, ■(_a_ × 10), and ■(_a_ × 100)) (_a_ being less than 10 and not less than 1) are given simultaneously and without any uncertainty as to the scales to use or the values to be read off.

To Find the Cube of a Number.—The marks II. and III. on D divide that scale into three equal sections. If the number to be cubed is in the first section, I. on C is set to it; if in the second section, II. on C is set to it; if in the third section, III. on C is set to it. Then, under the index mark on the back of the slide will be found the significant figures of the cube on the scale F. If I. on C was used for the setting, the cube contains 1 digit; if II. was used, 2 digits; if III. was used, 3 digits. If the first figure of the number to be cubed is not in the units place, the decimal point is moved through _n_ places so as to bring the first significant figure into the units place, the cube found as above, and the decimal point moved in the _reverse direction_ through 3_n_ places.

To Find the Cube Root of a Number.—The index mark is set to the significant figures of the number on scale F, and the cube root is read on D under I., II. or III. on C, according as the number has 1, 2 or 3 digits preceding the decimal point. Numbers which have 1, 2 or 3 figures preceding the decimal point are dealt with directly. Numbers of any other form are brought to one of the above forms by moving the decimal point 3 places (or such multiple of 3 places as may be required), the root found and its decimal point moved 1 place for each 3-place movement, but in the _reverse direction_.

THE “ELECTRO” SLIDE RULE.—In this special rule for electrical calculations, made by Mr. A. Nestler, the upper scales run from 0·1 to 1000, and are marked “Amp.” and “sq. mm.” respectively. The lower scale on the slide running from 1 to 10,000 is marked M (metres), while the lower scale on the rule (0·1 to 100) is marked “Volt.” The latter scale is so displaced that 10 on M agrees with 0·173 on the Volt scale. The four factors involved are the current strength (in Amp.); the area of a conductor (in sq. mm.); the length of the conductor (in metres); and the permissible loss of potential (in volts). Having given any three of these, the fourth can be found very readily. On the back of the slide are a scale of squares, a scale of cubes and a single scale corresponding to the D scale of an ordinary rule. Hence, by reversing the slide, it is possible to obtain the 2nd, 3rd and 4th powers and roots of numbers. In another form of the rule, the scale of metres is replaced by one of yards, while instead of the area of the conductor in sq. mm., the corresponding “gauge” sizes of wires are given.

THE “POLYPHASE” SLIDE RULE.—This instrument, made by the Keuffel & Esser Company, New York, has, in addition to the usual scales, a scale of cubes on the vertical edge of the stock of the rule, while in the centre of the slide there is a reversed C scale; _i.e._, a scale exactly similar to an ordinary C scale but with the graduations running from right to left. The rule is specially useful for the solution of problems containing combinations of three factors and problems involving squares, square roots, cubes, cube roots and many of the higher powers and roots. It is specially adapted for electrical and hydraulic work.

THE LOG-LOG DUPLEX SLIDE RULE.—The same makers have introduced a log-log duplex slide rule, in which the log-log scale is in three sections, placed one above the other, these occupying the position usually taken up by the A scale. These scales are used in the manner already described (page 86), but some advantage is obtained by the manner in which the complete log-log scale is divided, the limits being _e_^{1/■■■} to _e_^■ (on Scale L.L. 1); _e_^■ to _e_ (on Scale L.L. 2); and _e_ to _e_^{10} (on Scale L.L. 3), _e_ being the base of natural or hyperbolic logarithms (2·71828). In this way a total log-log range of from 1·01 to 22,000 is provided, meeting all practical requirements. These log-log scales are read in conjunction with a C scale placed at the upper edge of the slide. A similar C scale, but reversed in direction, is placed at the lower edge of the slide, this having red figures to distinguish it readily. The adjacent scale on the body of the rule is an ordinary D scale, and under this is an equally-divided scale giving the common logarithms of values on D. In the centre of the slide is a scale of tangents.

It will be understood that a “duplex” rule consists of two side strips securely clamped together at the two ends, forming the body of the rule, the slide moving between them; hence both front and back faces of the rule and slide are available, graduations on the one side being referred to those on the other by the cursor which extends around the whole. In this instrument, the scales on the back face are the ordinary scales of the standard rule with the addition of a scale of sines which is placed in the centre of the slide. It will be evident that this instrument is capable of dealing with a very wide range of problems involving exponential and trigonometrical formulæ.

SMALL SLIDE RULES WITH MAGNIFYING CURSORS.—Several makers now supply 5 in. rules having the full graduations of a 10 in. rule, and fitted with a magnifying cursor (Fig. 34). This forms a compact instrument for the pocket, but owing to the closeness of the graduations it is not usually possible to make a setting of the slide without using the cursor. This, of course, involves more movements than with the ordinary instrument. It is also very necessary to use the magnifying cursor in a _direct_ light, if accurate readings are to be obtained. If these slight inconveniences are to be tolerated, the principle could be extended, a 10 in. rule being marked as fully as a 20 in., and fitted with a magnifying cursor. The author has endeavoured, but without success, to induce makers to introduce such a rule.

The magnifying cursor, supplied by Messrs. A. G. Thornton, Limited, has a lens which fills the entire cursor. It has a powerful magnifying effect, and the change from the natural to the magnified reading is less abrupt than with the semicircular lens.

[Illustration: FIG. 34.]

THE CHEMIST’S SLIDE RULE.—A slide rule, specially adapted for chemical calculations, has been introduced recently by Mr. A. Nestler. In this instrument the C and D scales are as usually arranged; but, in place of the A and B scales, there are a number of gauge points or marks denoting the atomic and molecular weights of the most important elements and combinations. The scales on the back of the slide are similarly arranged, so that by reversing the slide the operations can be extended very considerably. The rule finds its chief use in the calculation of analyses. Thus, to find the percentage of chlorine if _s_ grammes of a substance have been used and the precipitate of Ag.Cl. weighs _a_ grammes, we have the equation, _x_ = (Cl.)/(Ag.Cl.) × (_a_)/(_s_). Hence, the mark Ag.Cl. on the upper scale of the slide is set to the mark Cl. on the upper scale of the rule, when under _a_ on the C scale is found the quantity of chlorine on D. By setting the cursor to this value and bringing _s_ on C to the cursor, the percentage required can be read on C over 10 on D.

The rule is also adapted to the solution of various other chemical and electro-chemical calculations.

THE STELFOX SLIDE RULE.—This rule, shown in Fig. 35, has a stock 5 in. long, fitted with a 10 in. slide jointed in the middle of its length by means of long dowels. By separating the parts the compactness of a 5 in. rule is obtained. The upper scales on the rule and slide resemble the usual A and B scales. The D scale on the lower part of the stock is in two sections, the second portion being placed below the first, as shown in the illustration. The centre scale on the slide corresponds to the usual C scale, while on the lower edge of the slide is a similar scale, but with the index (1) in the middle of its length. The arrangement avoids the necessity of resetting the slide, as is sometimes necessary with the ordinary rule, and in general it combines the accuracy of a 10 in. rule with the compactness of a 5 in. rule; but a more frequent use of the cursor is necessary. This rule is made by Messrs. John Davis & Son, Limited, Derby.

[Illustration: FIG. 35.]

ELECTRICAL SLIDE RULE.—Another rule by the same makers, specially useful for electrical engineers, has the usual scales on the working edges of the rule and slide, while in the middle of the slide is placed a scale of cubes. A log-log scale in two sections is

provided; the power portion, running from 1·07 to 2, is found on the lower part of the stock, and the upper portion, running from 2 to 10^3, on the upper part of the stock. The uppermost scale on the stock is in two parts, of which that to the left, running from 20 to 100 and marked “Dynamo,” gives the efficiencies of dynamos; that on the right, running from 20 to 100 and marked “Motor,” gives the efficiencies of electric motors. The lowest scale on the stock, marked “Volt,” gives the loss of potential in copper conductors. The ordinary upper scale on the stock is marked L (length of lead) at the left, and KW (kilowatts) at the right; the ordinary upper scale on the slide is marked A (ampères) and mm^2 (sectional area) at the left, and HP (horse-power) at the right. Additional lines on the cursor enable the electrical calculations to be made either in British or metric units.

THE PICOLET CIRCULAR SLIDE RULE.—A simple form of circular calculator, made by Mr. L. E. Picolet of Philadelphia, is shown in Fig. 36. It consists of a base disc of stout celluloid on which turns a smaller disc of thin celluloid. A cursor formed of transparent celluloid is folded over the discs, and is attached so that the friction between the cursor and the inner disc enables the latter to be turned by moving the former. By holding both discs the cursor can be adjusted as required. The adjacent scales run in opposite directions, so that multiplication and division are performed as with the inverted slide in an ordinary rule. The outer scale, which is two-thirds the length of the main scale, enables cube roots to be found. Square roots are readily determined and continuous multiplication and division conveniently effected. Modified forms of this neatly made little instrument are also available.

[Illustration: FIG. 36.]

OTHER RECENT SLIDE RULES.—Among other special types of slide rule, mention should be made of the _Jakin_ 10 in. rule for surveyors, made by Messrs. John Davis & Son, Limited, Derby. By the provision of a series of short subsidiary scales, the multiplication of a sine or tangent of an angle by a number can be obtained to an accuracy of 1 in 10,000. The _Davis-Lee-Bottomley_ slide rule, by the same makers, has special scales provided for circle spacing. The division of a circle into a number of equal parts, often required in spacing rivets, bolts, etc., and in setting out the teeth of gearwheels, is readily effected by the aid of this instrument. The _Cuntz_ slide rule is a very comprehensive instrument, having a stock about 2¼ in. wide, with the slide near the lower edge. Above the slide are eleven scales, referable to the main scales by the cursor. These scales enable squares and square roots, cubes and cube roots, and areas and circumferences of circles to be obtained by direct reading. A much more compact instrument could be obtained by removing one-half the scales to the back of the rule and using a double cursor.

[Illustration: FIG. 37.]

In one form of 10 in. rule, supplied by Mr. W. H. Harling, London, the body of the rule is made of well-seasoned cane, with the usual celluloid facings. The rule has a metal back, enabling the fit of the slide to be regulated. This backing extends the full length of the rule, openings about 1 in. long being provided at each end, enabling the scales on the back of the slide to be set with greater facility than is possible with the notched recesses usually adopted. The author has long endeavoured, but without success, to induce makers to fit windows of glass or celluloid in place of the notched recesses. This would allow the graduation of the S and T scales to be set more accurately, and enable both to be used at each end of the rule—an advantage in certain trigonometrical calculations. It would have the further advantage of permitting each alternate graduation of the evenly-divided or logarithm scale to be placed at opposite sides of one central line, enabling the reading to be made more accurately and conveniently.

Many special slide rules have lately been devised for determining the time necessary to perform various machine-tool operations and for analogous purposes, while attention has again been given to rules for calculating the weights of iron and steel bars, plates, etc.

THE DAVIS-STOKES FIELD GUNNERY SLIDE RULE.—This rule, which is adapted for calculations involved in “encounter” and “entrenched” field gunnery, is designed for the 18 pr. quick-firing gun. The upper and lower portions of the boxwood stock are united by a flexible centre of celluloid, thus providing grooves front and rear to receive boxwood slides. Each of the nineteen scales is marked with its name, and corresponding scales are coloured red or black. The front edge is bevelled and carries a scale of 1 in 20,000. The rule solves displacement problems, map angles of sight, changes of corrector and range corrections for changes in temperature, wind and barometer, etc. A special feature for displacement calculations is the provision of a 50 yd. sub-base angle scale, by which the apex angle is read at one setting.

THE DAVIS-MARTIN WIRELESS SLIDE RULE.—In wireless telegraphy it is frequently necessary to determine wave-length, capacity or self-induction when one or other of the factors of the equation, $\lambda = 59{\cdot}6\sqrt{(LC)}$ is unknown. The Davis-Martin wireless rule is designed to simplify such calculations. The upper scale in the stock (inductance) runs from 10,000 to 1,000,000; the adjacent scale on the slide (capacity) runs from 0·0001 to 0·01 but in the reverse direction. The lower scale on the stock (wave-length) runs

from 100 to 1000, giving square roots of the upper scale; while on the lower edge of the scale are several arrows to suit the various denominations in which the wave-length and capacity may be expressed.

IMPROVED CURSORS.—In some slide-rule operations, notably in those involved in solving quadratic and cubic equations, it not infrequently happens that readings are obscured by the frame of the cursor. Frameless cursors have been introduced to obviate this defect. A piece of thick transparent celluloid is sometimes employed, but this is liable to become scratched in use. Fig. 37 shows a recent form of frameless glass cursor made by the Keuffel & Esser Company, Hoboken, N.J., which is satisfactory in every way.

Cursors having three hair lines are now fitted to some rules, the distance apart of the lines being equal to the interval 0·7854–1 on the A scale.

THE DAVIS-PLETTS SLIDE RULE.—In this rule a single log.-log. scale and its reciprocal scale are arranged opposite the ordinary upper log. scale. Thus, common logarithms can be read directly, while by taking advantage of the properties of characteristics and mantissas of common logarithms, the scale can be extended indefinitely. As 10 is the highest number on the log.-log. scale, it is carried down to within 0·025 of unity. The reading of log.-log. values above 10 is effected in a very simple manner. There is also a scale in the centre of the slide which, used in conjunction with the upper log. scale enables the natural logarithm of any number between 0·0001 and 10,000 to be read direct, while any number on the upper log. scale can be multiplied or divided by _e^x_ if the latter is between these limits. On the back of the slide are scales for all circular and hyperbolic functions, these being used in conjunction with the upper log. scales.

THE CROMPTON-GALLAGHER BOILER EFFICIENCY CALCULATOR has a stock in the thickness of which is a slot admitting a chart which can be moved at right angles to the two separate slides. On the bevelled edge of one slide, the graduations are continued so as to read against curves on the chart, through an opening in the stock.

THE DAVIS-GRINSTED COMPLEX CALCULATOR.—This slide rule is of considerable service in connection with calculations involving the conversion of complex quantities from the form _a_ + _j_ _b_ to the form R∠θ, and _vice versa_. The usual process of conversion necessitates repeated reference to trigonometrical tables, and is both tedious and time-taking. The Complex Calculator enables the conversions to be effected without reference to tables and with the minimum expenditure of time and labour.

The rule, which is about 16 in. long, has five scales. The upper one (A) is an ordinary logarithmic scale thrice-repeated. The adjacent scales on the slide comprise (1) a logarithmic scale of tangents (B) ranging from 0·1° to 45°, and (2) a logarithmic scale of secants (C) from 0° to 45°. The lower scales D and E are identical with the A scale, and are provided to enable multiplication, etc., to be performed without the need for a separate slide rule. Readings can be transferred from A to the lower scales by means of the cursor.

In using the rule to convert _a_ + _j_ _b_ to R∠θ, the index (45°) of the B scale is set to the larger component and the cursor to the smaller component, on scale A. Then θ (or its complement if _b_ is greater than _a_) is read on B under the cursor. The cursor is then set to θ on the C scale, and R is read on A under the cursor. The rule is made by Messrs. John Davis & Son, Limited, Derby.

THE SOLUTION OF ALGEBRAIC EQUATIONS.

The slide rule finds an interesting application in the solution of equations of the second and third degree; and although the process is essentially one of trial and error, it may often serve as an efficient substitute for the more laborious algebraic methods, particularly when the conditions of the problem or the operator's knowledge of the theory of equations enables some idea to be obtained as to the character of the result sought. The principle may be thus briefly explained:—If 1 on C is set to _x_ on D (Fig. 38), we find _x_(_x_) = _x_^2 on D under _x_ on C. If, however, with the slide set as before, instead of reading under _x_, we read under _x_ + _m_ on C, the result on D will now be _x_(_x_ + _m_) = _x_^2 + _mx_ = _q_. Hence to solve the equation _x_^2 + _mx_ – _q_ = 0, we reverse the above process, and setting the cursor to _q_ on D, we move the slide until the number on C under the cursor, and that on D under 1 on C, _differ by m_. It is obvious from the setting that the _product_ of these numbers = _q_, and as their difference = _m_, they are seen to be the roots of the equation as required. For the equation _x_^2 – _mx_ + _q_ = 0, we require _m_ to equal the _sum_ of the roots. Hence, setting the cursor as before to _q_ on D, we move the slide until the number on C under the cursor, and that on D under 1 on C, are _together equal to_ _m_, these numbers being the roots sought. The alternative equations _x_^2 – _mx_ – _q_ = 0, and _x_^2 + _mx_ + _q_ = 0 are deducible from the others by changing the signs of the roots, and need not be further considered.

[Illustration: FIG. 38.]

EX.—Find the roots of $x^2 - 8x + 9 = 0$.

Set the cursor to 9 on D, and move the slide to the right until when 6·64 is found under the cursor, 1·355 on D is under 1 on C. These numbers are the roots required.

The upper scales can of course be used; indeed, in general they are to be preferred.

EX.—Find the roots of $x^2 + 12{\cdot}8x + 39{\cdot}4 = 0$.

Set the cursor to 39·4 on A, and move the slide to the right until we read 7·65 on B under the cursor, and 5·15 on A over 1 on B. The roots are therefore –7·65 and –5.15.

With a little consideration of the relative value of the upper and lower scales, the student interested will readily perceive how equations of the third degree may be similarly resolved. The subject is not of sufficient general importance to warrant a detailed examination being made of the several expressions which can be dealt with in the manner suggested; but the author gives the following example as affording some indication of the adaptability of the method to practical calculations.

EX.—A hollow copper ball, 7·5 in. in diameter and 2 lb. in weight, floats in water. To what depth will it sink?

The water displaced = 27·7 × 2 = 55·4 cub. in. The cubic contents of the immersed segment will be $(\pi)/(3)(3r x^2 - x^3)$, r being the radius and x the depth of immersion. Hence $(\pi)/(3)(3r x^2 - x^3) = 55{\cdot}4$, and $11{\cdot}25x^2 - x^3 = 52{\cdot}9$.

To solve this equation we place the cursor to 52·9 on A, and move the slide until the reading on D under 1 and that on B under the cursor together amount to 11·25. In this way find 2·45 on D under 1, with 8·8 on B under the cursor c, c, as a pair of values of which the sum is 11·25. Hence we conclude that $x = 2{\cdot}45$ in. is the result sought.

With the rule thus set (Fig. 39) the student will note that the slide is displaced to the right by an amount which represents x on D, and therefore x^2 on A; while the length on B from 1 to the cursor line represents $11{\cdot}25 - x$. Hence the upper scale setting gives $x^2(11{\cdot}25 - x) = 11{\cdot}25x^2 - x^3 = 52{\cdot}9$ as required.

[Illustration: FIG. 39.]

When in doubt as to the method to be pursued in any given case, the student should work synthetically, building up a simple example of an analogous character to that under consideration, and so deducing the plan to be followed in the reverse process.

SCREW-CUTTING GEAR CALCULATIONS.

The slide rule has long found a useful application in connection with the gear calculations necessary in screw-cutting, helical gear-cutting, and spiral gear work.

SINGLE GEARS.—For simple cases of screw-cutting in the lathe it is only necessary to set the threads per inch to be cut to the threads per inch in the guide screw (or the pitch in inches in each case, if more convenient). Then any pair of coinciding values on the two scales will give possible pairs of wheels.

EX.—Find wheels to cut a screw of 1■ threads per inch with a guide screw of 2 threads per inch.

Setting 1·625 on C to 2 on D, it is seen that 80 (driver) and 65 (driven) are possible wheels.

COMPOUND GEARS.—When wheels so found are of inconvenient size, a compound train is used, consisting (usually) of two drivers and two driven wheels, the product of the two former and the product of the two latter being in the same ratio as the simple wheels. Thus with 60 and 40 as drivers, and 65 and 30 as driven, we have, $(60 \times 40)/(65 \times 30) = (2400)/(1950) = (2)/(1{\cdot}625)$ as before.

With the slide set as above, values convenient for splitting up into suitable wheels are readily obtainable. Thus, (1600)/(1300); (2400)/(1950); (4000)/(3250); (4800)/(3900) are a few suggestive values which may be readily factorised.

SLIDE RULES FOR SCREW-CUTTING CALCULATIONS.—Special circular and straight slide rules for screw-cutting gear calculations have long been employed. For compound gears these usually entail the use of six scales, two on each of the two slides and two on the stock. The upper scale on the stock may be a scale of threads per inch to be cut, the adjacent scale (on the upper slide) a scale of threads per inch in the guide screw. Setting the guide screw-graduation to the threads to be cut, the lower slide is adjusted until a convenient pair of drivers is found in coincidence on the central pair of scales, while a pair of driven wheels are in coincidence on the two lower scales.

Some years ago, a slide rule was introduced by which compound gears could be obtained with a single slide. Assuming the set of wheels usually provided—20 to 120 teeth advancing by 5 teeth—the products of 20 × 25, 20 × 30, etc., up to 115 × 120 were calculated. These products were laid out along each of the two lower scales. The upper scales were a scale of threads per inch to be cut and a scale of the threads per inch of various guide screws. Setting the guide screw-graduation to the threads to be cut, any coinciding graduations on the lower scales gave the required pairs of drivers and driven wheels.

FRACTIONAL PITCH CALCULATIONS.—The author has long advocated the use of the slide rule for determining the wheels necessary for cutting fractional pitch threads, and it is gratifying to find its value in this connection is now being appreciated. For the best results a good 20 in. rule is desirable, but with care very close approximations can be found with an accurate 10 in. rule. In any case a magnifying cursor or a hand reading-glass is of great assistance.

EX.—Find wheels to cut a thread of 0·70909 in. pitch; guide screw, 2 threads per inch.

To 0·70909 on D, set 0·5 (guide screw pitch in inches) on C. To make this setting as accurately as possible, the method described on page 112 may be used. Set 10 on C to about 91 on D, and note that the interval 77–78 on C represents 0·91 of the interval 70–71 on D. Set the cursor to 78 on C and bring 5 to the cursor. The slide is then set so that 5 on C agrees with 7·091 on D.

Inspection of the two scales shows various coinciding factors in the ratio required. The most accurate is seen to be (55 on C)/(78 on D). These values may be split up into (55 × 50)/(65 × 60) to form a suitable compound train of gears.

GAUGE POINTS AND SIGNS ON SLIDE RULES.

Many slide rules have the sign (Prod.)/(–1) at the right-hand end of the D scale, while on the left is (Quot.)/(+1.) It is somewhat unfortunate that these signs refer to rules for determining the number of digits in products and quotients, which are used to a considerable extent on the Continent, and conflict with those used in this country. By the Continental method the number of digits in a product is equal to the sum of the digits in the two factors, if the result is obtained on the LEFT _of the first factor_; but if the result is found on the RIGHT of the first factor, it is equal to this sum – 1. The sign (Prod.)/(–1) the _right_-hand end of the D scale provides a visible reminder of this rule.

Similarly for division:—The number of digits in a quotient is equal to the number of the digits in the dividend, minus those in the divisor, if the quotient appears on the RIGHT _of the dividend_, and to this difference + 1, if the quotient appears on the LEFT of the dividend. The sign (Quot.)/(+1) at the _left_-hand end of the D scale provides a visible reminder of this rule.

The sign

+■– ■■■ –■+

found at both ends of the A scale is of general application but of questionable utility. It is assumed to represent a fraction, the vertical line indicating the position of the decimal point. If the number 455 is to be dealt with in a multiplication on the lower scales, we may suppose the decimal point moved two places to the left, giving 4·55, a value which can be actually found on the scale. If we use this value, then to the number of digits in this result, as many must be added as the number of places (two in this case) by which the decimal point was moved. If the point is moved to the right, the number of places must be subtracted. Similarly, in division, if the decimal point in the divisor is moved _n_ places to the left, then _n_ places must be subtracted at the end of the operation; while if the point is moved through _n_ places to the right, then _n_ places must be added. The sign referred to, which, of course, applies to all scales, completely indicates these processes and is submitted as a reminder of the procedure to be followed by those using the method described.

The signs π, _c_, _c′_, and M are explained in the Section on “Gauge Points,” p. 53.

On some rules additional signs are found on the D scale. One, locating the value (180 × 60)/(π) = 3437·74 and hence giving the number of minutes in a radian, is marked ρ′. Another, representing the value (180 × 60 × 60)/(π) = 206265, and hence giving the number of seconds in a radian is marked ρ″. A third point, marked ρ_{■}, placed at the value (200 × 100 × 100)/(π) = 636620, is used when the newer graduation of the circle is employed.

These gauge points are useful when converting angles into circular measure, or _vice versa_, and also for determining the functions of small angles.

A gauge point is sometimes marked at 1146 on the A and B scales. This is known as the “Gunner’s Mark,” and is used in artillery calculations involving angles of less than 20°, when, for the purpose in view, the tangent and circular measure of the angle may be regarded as equal. For this constant, the angle is taken in minutes, the auxiliary base in feet, and the base in yards. The auxiliary base in feet on B is set to the angle in minutes on A when over 1146 on B is the base in yards on A. The value (1)/(1146) = (π × 3)/(180 × 60).

TABLES AND DATA.

MENSURATION FORMULAE.

Area of a parallelogram = base × height.

Area of rhombus = ½ product of the diagonals.

Area of a triangle = ½ base × perpendicular height.

Area of equilateral triangle = square of side × 0·433.

Area of trapezium = ½ sum of two parallel sides × height.

Area of any right-lined figure of four or more unequal sides is found by dividing it into triangles, finding area of each and adding together.

Area of regular polygon = (1) length of one side × number of sides × radius of inscribed circle; or (2) the sum of the triangular areas into which the figures may be divided.

Circumference of a circle = diameter × 3·1416.

Circumference of circle circumscribing a square = side × 4·443.

Circumference of circle = side of equal square × 3·545.

Length of arc of circle = radius × degrees in arc × 0·01745.

Area of a circle = square of diameter × 0·7854.

Area of sector of a circle = length of arc × ½ radius.

Area of segment of a circle = area of sector – area of triangle.

Side of square of area equal to a circle = diameter × 0·8862.

Diameter of circle equal in area to square = side of square × 1·1284.

Side of square inscribed in circle = diameter of circle × 0·707.

Diameter of circle circumscribing a square = side of square × 1·414.

Area of square = area of inscribed circle × 1·2732.

Area of circle circumscribing square = square of side × 1·5708.

Area of square = area of circumscribing circle × 0·6366.

Area of a parabola = base x ■ height.

Area of an ellipse = major axis × minor axis × 0·7854.

Surface of prism or cylinder = (area of two ends) + (length × perimeter).

Volume of prism or cylinder = area of base × height.

Surface of pyramid or cone = ½(slant height × perimeter of base) + area of base.

Volume of pyramid or cone = (■)(area of base × perpendicular height).

Surface of sphere = square of diameter × 3·1416.

Volume of sphere = cube of diameter × 0·5236.

Volume of hexagonal prism = square of side × 2·598 × height.

Volume of paraboloid = ½ volume of circumscribing cylinder.

Volume of ring (circular section) = mean diameter of ring × 2·47 × square of diameter of section.

4 inch Spring Bow Half Set centre screw adjustment, with interchangeable needle, pen, and pencil points Price 17/6

The Centre Screw Spring Bow Half Set of Compasses, as illustrated, possesses the advantage of COMBINING IN ONE INSTRUMENT THE SET OF THREE SEPARATE SPRING BOWS hitherto in use, while the centre screw makes for ease and accuracy of manipulation, at the same time providing a radius of over 2 inches, or double that of the old pattern.

This instrument is less expensive than the set of 3 bows, while considerably stronger in construction.

The fixed needle point is shouldered.

This illustration is given as an indication of the various Drawing Instruments manufactured by us.

Illustrated Booklet giving full particulars and prices of other Instruments and Cases of Instruments sent on application.

Underscores "_" before and after a word or phrase indicate _italics_ in the original text. Equal signs "=" before and after a word or phrase indicate =bold= in the original text. Small capitals have been converted to SOLID capitals. Illustrations have been moved so they do not break up paragraphs. Deprecated spellings have been preserved. Typographical and punctuation errors have been silently corrected.

ANCIENT AND MODERN ENGINEERING

AND THE ISTHMIAN CANAL.

BY WILLIAM H. BURR, C.E.,

Professor of Civil-Engineering in Columbia University; Member of the American Society of Civil Engineers and of the Institution of Civil Engineers of Great Britain.

FIRST EDITION. FIRST THOUSAND.

NEW YORK: JOHN WILEY & SONS. LONDON: CHAPMAN & HALL, LIMITED. 1903.

Copyright, 1902, BY WILLIAM H. BURR

ROBERT DRUMMOND, PRINTER, NEW YORK.

INTRODUCTION.

This book is the outcome of a course of six lectures delivered at the Cooper Union in the city of New York in February and March, 1902, under the auspices of Columbia University. It seemed desirable by the President of the University that the subject-matter of the lectures should be prepared for ultimate publication. The six Parts of the book, therefore, comprise the substance of the six lectures, suitably expanded for the purposes of publication.

It may be interesting to state that the half-tone illustrations have, with scarcely an exception, been prepared from photographs of the actual subjects illustrated. All such illustrations in Parts V and VI devoted to the Nicaragua and Panama Canal routes are made from photographs at the various locations by members of the force of the Isthmian Canal Commission; they are, therefore, absolutely true representations of the actual localities to which they apply.

For other illustrations the author wishes to express his indebtedness to Messrs. G. P. Putnam's Sons, Messrs. Turneaure and Russell, John Wiley & Sons, The Morrison-Jewell Filtration Company, Mr. H. M. Sperry, Signal Engineer, _The Engineering News_, _The Railroad Gazette_, The American Society of Civil Engineers, The Standard Switch and Signal Company, The Baldwin Locomotive Works, the American Locomotive Works, Mr. Clemens Herschel, and the International Pump Company, and to others from whom the author has received courtesies which he deeply appreciates.

The classification or division of the matter of the text, and the table of contents, have been made so complete, with a view to convenience even of the desultory reader in seeking any particular subject or paragraph, that no index has been prepared, as it is believed that the table of contents, as arranged, practically supplies the information ordinarily given by a comprehensive index.

Complete and detailed treatments of the purely technical matters covered by Part II will be found in the author's "Elasticity and Resistance of Materials" and in his "Stresses in Bridge and Roof Trusses, Arched Ribs and Suspension Bridges."

W. H. B.

COLUMBIA UNIVERSITY, October 24, 1902.

PART I.

ANCIENT CIVIL-ENGINEERING WORKS.

CHAPTER I.

=1. Introductory.=—It is a common impression even among civil engineers that their profession is of modern origin, and it is frequently called the youngest of the professions. That impression is erroneous from every point of view. Many engineering works of magnitude and of great importance to the people whom they served were executed in the very dawn of history, and they have been followed by many other works of at least equal magnitude and under circumstances scarcely less noteworthy, of which we have either remains or records. During the lapse of the arts and of almost every process of civilization throughout the darkness of the Middle Ages there was little if any progress made in the art of the engineer, and what little was done was executed almost entirely under the name of architecture. With the revival of intellectual activity and with the development of science the value of its practical application to the growing nations of the civilized world caused the modern profession of civil-engineering to take definite shape and to be known by the name which it now carries, but which was not known to ancient peoples. Unfortunately the beginnings of engineering cannot be traced; there is no historical record running back far enough to render account of the earliest engineering works whose ruins remain as enduring evidence of what was then accomplished.

It is probably correct to state that the material progress of any people has always been concurrent with the development of the art of civil-engineering, and, hence, that the practice of civil engineering began among the people who made the earliest progress in civilization, to whom "the art of directing the Great Sources of Power in Nature for the use and convenience of man" became an early and imperative necessity. Indeed that conclusion is confirmed by the most ancient ruins of what may be termed public works that archæological investigations have revealed to us, among which are those to be found in the Chaldean region, in India, and in Egypt. Obviously, anything like a detailed account of the structural and other works of such ancient character must be lacking, as

some of them were built before even the beginnings of history. Our only data, therefore, are the remains of such works, and unfortunately they have too frequently been subject to the destructive operations of both man and nature.

=2. Hydraulic Works of Chaldea and Egypt.=—It is absolutely certain that the populous centres of prehistoric times could not have existed nor have been served with those means of communication imperatively necessary to their welfare without the practice of the art of engineering, under whatever name they may have applied to it. It is known beyond any doubt that the anciently populous and prosperous country at the head of the Persian Gulf and watered by the Euphrates and the Tigris was irrigated and served by a most complete system of canals, and the same observation can be made in reference to the valley of the Nile. It is not possible at this period of that country's history to determine to what extent irrigation was practised or how extensively the former country was served by water transportation conducted along artificial channels; but hydraulic works, including dams and sluices with other regulating appliances designed to bring waters from the rivers on to the land, were certainly among the earliest executed for the benefit of the communities inhabiting those regions. The remains of those works, spread over a large territory in the vicinity of ancient Babylon, Nippur, and other centres of population, show beyond the slightest doubt that there existed a network of water communication throughout what was in those days a country rich in agricultural products and which supported the operations of a most prosperous commerce. These canals were of ample dimensions to float boats of no mean size, although much smaller than those occupied in our larger systems of canal transportation. They were many miles in length, frequently interlacing among themselves and intersecting both the Tigris and the Euphrates. The remains of these canals, some of them still containing water, show that they must originally have been filled to depths varying from five or six to fifteen or twenty feet, and that their widths may have been twenty-five or thirty feet or more. Another curious feature is their occasional arrangement in twos and threes alongside of each other with embankments only between. The entire Euphrates-Tigris valley from the head of the Persian Gulf at least to modern Baghdad (i.e., Babylonia) and possibly to ancient Nineveh was served by these artificial waterways. Later, when Alexander the Great made one of his victorious expeditions through the Assyrian country, he found in the Tigris obstructions to the passage of his ships down-stream in the shape of masonry dams. This was between 356 and 322 B.C. These substantial dams were built across the river for the purpose of intakes to irrigating-canals for the benefit of the adjacent country. These canals, like those of Egypt, were fitted with all the necessary regulating-devices of sluices or gates, both of a crude character, but evidently sufficiently effective for their purpose.

[Illustration]

It is known that there were in those early days interchanges of large amounts and varieties of commodities, and it is almost if not quite certain that the countries tributary to the Persian Gulf not only produced sufficient grain for their own needs, but also carried on considerable commerce with the Asiatic coast. We have no means of ascertaining either the volume or the precise character of the traffic, but there is little or no doubt of its existence. It is established also that the waters of the Red Sea and the Nile were connected by a canal about 1450 B.C. Recent investigations about Nippur and other sites of ancient cities in that region confirm other indications that the practice of some branches of hydraulic engineering had received material development from possibly two to four thousand years before the Christian era.

=3. Structural Works in Chaldea and Egypt.=—The ruins of ancient buildings which have been unearthed by excavations in the same vicinity show with the same degree of certainty that the art of constructing buildings of considerable dimensions had also made material progress at the same time, and in many cases must have involved engineering considerations of a decided character both as to structural materials and to foundations. Bricks were manufactured and used. Stones were quarried and dressed for building purposes and applied so as to produce structural results of considerable excellence. Even the arch was probably used to some extent in that locality in those early days, but stone and timber beams were constantly employed. In the prehistoric masonry constructions of both the Egyptians and Chaldeans and probably other prehistoric peoples, lime or cement mortar was not employed, but came into use at a subsequent period when the properties of lime and cement as cementing materials began to be recognized. The first cementing material probably used in Egypt was a sticky clay, or possibly a calcareous clay or earth. The same material was also used in the valley of the Euphrates, but in the latter country there are springs of bitumen, where that material exudes from the earth in large quantities. The use of this asphaltic cement at times possibly involved that of sand or gravel in some of the early constructions. Later, lime mortar and possibly a weak hydraulic cement came to be employed, although there is little if any evidence of the latter material.

Iron was manufactured and used at least in small quantities, and for some structural purposes, even though in a crude manner. Bituminous or other asphaltic material was found as a natural product at various points, and its value for certain structural purposes

was well known; it was used both for waterproofing and for cement. It is practically certain that the construction of engineering works whose interesting ruins still remain involved a considerable number of affiliated engineering operations of which no evidence has yet been found, and of the employment of tools and appliances of which we have no record. So far as these works were of a public character they were constructed by the aid of a very different labor system from that now existing. The kings or ruling potentates of those early times were clothed with the most arbitrary authority, sometimes exercised wisely in the best interests of their people, but at other times the ruling motive was selfishness actuated by the most intense egotism and brutal tyranny. Hence all public works were executed practically as royal enterprises and chiefly by forced labor, perhaps generally without compensation except mere sustenance. Under such conditions it was possible to construct works on a scale out of all proportion to national usefulness and without structural economy. When it is remembered that these conditions existed without even the shadow of engineering science, it is obvious that structural economy or the adaptation of well-considered means to an end will not be found to characterize engineering operations of prehistoric times. Nevertheless there are evidences of good judgment and reasonable engineering design found in connection with some of these works, particularly with those of an hydraulic character. Water was lifted or pumped by spiral or screw machines and by water-wheels, and it is not improbable that other appliances of power served the purposes of many industrial and crude manufacturing operations which it is now impossible for us to determine.

[Illustration: FIG. 1.—Home Built on Piles in the Land of Punt.]

It is an interesting fact that while many ancient works were exceedingly massive, like the pyramids, the largest of those of which the ruins have been preserved seldom seem to show little or any evidence of serious settlement. Whether the ancients had unusually sound ideas as to the design of foundation works, or whether those only have come down to us that were founded directly upon rock, we have scarcely any means of deciding. Nor can we determine at this time what special recourses were available for foundation work on soft ground. Probably one of the earliest recognized instances, if not the earliest, of the building of structures on piles is that given by Sir George Rawlinson, when he states that a fleet of merchant vessels sent down the northeast African coast by the Egyptian queen Hatasu, probably 1700 B.C. or 1600 B.C., found a people whose huts were supported on piles in order to raise them above the marshy ground and possibly for additional safety. A representation (Fig. 1) of one of these native homes on piles is found among Egyptian hieroglyphics of the period of Queen Hatasu.

=4. Ancient Maritime Commerce.=—It is well known that both the Chaldean region and the Nile valley and delta, at least from Ethiopia to the Mediterranean Sea, were densely populated during the period of two to four or five thousand years before the Christian era. By means of the irrigation works to which reference has already been made both lands became highly productive, and it is also well known that those peoples carried on a considerable commerce with other countries, as did the Phœnicians also, at least between the innumerable wars which seemed to be the main business of states in those days. These commercial operations required not only the construction of fleets of what seem to us small vessels for such purposes, but also harbor-works at least suitable to the vessels then in use. The marine activity of the Phœnicians is undoubted, and there is strong reason to believe that there was also similar activity between Babylonian ports and those east of them along the shores of the Indian Ocean, perhaps even as far as ancient Cathay, and possibly also to the eastern coast of Africa.

Investigations in the early history of Egypt have shown that a Phœnician fleet, constructed at some Egyptian port on the Red Sea, undoubtedly made the complete circuit of Africa and returned to Egypt through the Mediterranean Sea the third year after setting out, over 2100 years (about 600 B.C.) before the historic fleet of the Portuguese explorer Vasco da Gama sailed the same circuit in the opposite direction. It is therefore probable, in view of these facts, that at least simple harbor-works of sufficient efficiency for those early days found place in the public works of the ancient kingdoms bordering upon the Mediterranean and Red seas and the Persian Gulf.

=5. The Change of the Nile Channel at Memphis.=—Although such obscure accounts as can be gathered in connection with the founding of the city of Memphis are so shadowy as to be largely legendary, it has been established beyond much if any doubt that prior to its building the reigning Egyptian monarch determined to change the course of the Nile so as to make it flow on the easterly side of the valley instead of the westerly. This was for the purpose of securing ample space for his city on the west of the river, and, also, that the latter might furnish a defence towards the east, from which direction invading enemies usually approached. He accordingly formed an immense dam or dike across the Nile as it then existed, and compelled it to change its course near the foot of the Libyan Hills on the west and seek a new channel nearer the easterly side of the valley. This must have been an engineering work of almost appalling magnitude in those early times, yet even with the crude means and limited resources of that early period, possibly, if not probably, at least 5000 B.C., the work was successfully accomplished.

=6. The Pyramids.=—Among the most prominent ancient structural works are the pyramids of Egypt, those royal tombs of which so much has been written. These are found chiefly in the immediate vicinity of Memphis on the Nile. There are sixty or seventy of them in all, the first of which was built by the Egyptian king Khufu and is known as the “Great Pyramid” or the “First Pyramid of Ghizeh.” They have been called “the most prodigious of all human constructions.” Their ages are uncertain, but they probably date from about 4000 B.C. to about 2500 B.C. These are antedated, however, by two Egyptian pyramidal constructions of still more ancient character whose ages cannot be determined, one at Meydoum and the other at Saccarah.

[Illustration: A Corner of the Great Pyramid.

(Copyright by S. S. McClure Co., 1902. Courtesy of _McClure’s Magazine_.)]

[Illustration: FIG. 2.—Section of the Great Pyramid.]

[Illustration: FIG. 3.]

The pyramids at Memphis are constructed of limestone and granite, the latter being the prominent material and used entirely for certain portions of the pyramids where the stone would be subjected to severe duty. The great mass of most of the pyramids consists of roughly hewn or squared blocks with little of any material properly considered mortar. The interior portions, especially of the later pyramids, were sometimes partially composed of chips, rough stones, mud bricks, or even mud, cellular retaining-walls being used in the latter cases for the main structural features. In all pyramids, however, the outer or exposed surfaces and the walls and roofs of all interior chambers were finished with finely jointed large stones, perhaps usually polished. The Great Pyramid has a square base, which was originally 764 feet on a side, with a height of apex above the surface of the ground of over 480 feet. This great mass of masonry contains about 3,500,000 cubic yards and weighs nearly 7,000,000 tons. The area of its base is 13.4 acres. The Greek historian Herodotus states that its construction required the labor of 100,000 men for twenty years. An enormous quantity of granite was required to be transported about 500 miles down the Nile from the quarries at Syene. Some of the blocks at the base are 30 feet long with a cross-section of 5 feet by 4 or 5 feet. The bulk of the entire mass is of comparatively small stones, although so squared and dressed as to fit closely together. Familiar descriptions of this work have told us that the small passages leading from the exterior to the sepulchral chambers are placed nearly in a vertical plane through the apex. The highest or king’s chamber, as it is called, measures 34 feet by 17 feet and is 19 feet high, and in it is placed the sarcophagus of King Khufu. It is composed entirely of granite most exactly cut and fitted and beautifully polished. The construction of the roof is remarkable, as it is composed of nine great blocks “each nearly 19 feet long and 4 feet wide, which are laid side by side upon the walls so as to form a complete ceiling.” There is a singular feature of construction of this ceiling designed to remove all pressure from it and consisting of five alternate open spaces and blocks of granite placed in vertical series, the highest open space being roofed over with inclined granite slabs leaning or strutted against each other like the letter V inverted. This arrangement relieves the ceiling of the sepulchral chamber from all pressure; indeed only the inclined highest set of granite blocks or slabs carry any load besides their own weight. There are two small ventilating- or air-shafts running in about equally inclined directions upward from the king’s chamber to the north and south faces of the pyramid. These air-shafts are square and vary between 6 and 9 inches on a side. The age of this pyramid is probably not far from 5000 years.

[Illustration: Entrance to the Great Pyramid.]

The second pyramid is not much inferior in size to the Great Pyramid, its base being a square of about 707 feet on a side, and its height about 454 feet. The remaining pyramids are much inferior in size, diminishing to comparatively small dimensions, and of materials much inferior to those used in the earlier and larger pyramids.

=7. Obelisks, Labyrinths, and Temples.=—Among other constructions of the Egyptians which may be called engineering in character, as well as architectural, are the obelisks, the “Labyrinth” so called, on the shore of Lake Mœris, and the magnificent temples at the ancient capital Thebes, which are the most remarkable architectural creations probably that the world has ever known. These latter were not completed by one king, as was each of the pyramids. They were sometimes despoiled and largely wrecked by invading hosts from Assyria, and then reconstructed in following periods by successive Egyptian kings and again added to by still subsequent monarchs, whose reigns were characterized by statesmanship, success in war, and prosperity in the country. Their construction conclusively indicates laborious operations and transportation of great blocks of stone characteristic of engineering development of the highest order for the days in which they took place. The dates of these constructions are by no means well defined, but they extend over the period running from probably about 2500 B.C. to about 400 B.C., with the summit of excellence about midway between.

Another class of ancient structures which can receive but a passing notice, although it deserves more, is the elaborate rock tombs of some of the old Egyptian monarchs in the rocks of the Libyan Hills. They were very extensive constructions and contained numerous successions of “passages, chambers, corridors, staircases, and pillared halls, each further removed from the entrance than the last, and all covered with an infinite number of brilliant paintings.” These tombs really constituted rock tunnels with complicated ramifications which must have added much to the difficulty of the work and required the exercise of engineering skill and resources of a high order.

[Illustration]

=8. Nile Irrigation.=—The value of the waters of the Nile for irrigation and fertilization were fully appreciated by the ancient Egyptians. They also apparently realized the national value of some means of equalizing the overflow, although the annual régimen of the Nile was unusually uniform. There were, however, periods of great depression throughout the whole Nile valley consequent upon the phenomenal failure of overflow to the normal extent. One of the earliest monarchs who was actuated by a fine public spirit undertook to solve the problem of providing against such depressions by diverting a portion of the flood-waters of the Nile into an enormous reservoir, so that during seasons of insufficient inundation the reservoir-waters could be drawn upon for the purpose of irrigation. This monarch is known as the good Amenemhat, although the Greeks call him Mœris. In the Nile valley, less than a hundred miles above Memphis, on the left side or to the west of the river, there is a gap in the Libyan Hills leading to an immense depression, the lower parts of which are much below the level of the water in the Nile. This topographical depression, perhaps 50 miles in length by 30 in breadth, with an area between 600 and 700 square miles, now contains two bodies of water or lakes, one known as the Birket Keroun and the other as Lake Mœris. The vicinity of this depression is called the Fayoum. A narrow rocky gorge connects it with the west branch of the Nile, known as Bahr el Yousuf, and it is probable that during extreme high water in the Nile there was a natural overflow into the Fayoum. The good Amenemhat, with the judgment of an engineer, or guided by advisers who possessed that judgment, appreciated the potential value of this natural depression as a possible reservoir for the surplus Nile waters and excavated a channel, possibly a natural channel enlarged, of suitable depth from it to the Bahr el Yousuf. As a consequence he secured a storage-reservoir of enormous capacity and which proved of inestimable value to the lowlands along the Nile in times of shortage in the river-floods.

Investigators have differed much in their conclusions as to the extent of this reservoir. Some have maintained that only the lower depressions of the Fayoum were filled for reservoir purposes, while others, like Mr. Cope Whitehouse, believe that the entire depression of the Fayoum was utilized with the exception of a few very high points, and that the depth of water might have been as much as 300 feet in some places. In the latter case the circuit of the lake would have been from 300 to 500 miles. Whatever may have been the size of the lake, however, its construction and use with its regulating-works was a piece of hydraulic engineering of the highest type, and it indicates an extraordinary development of that class of operations for the period in which it was executed. The exact date of this construction cannot be determined, but it may have been as early as 2000 B.C., or perhaps earlier.

=9. Prehistoric Bridge-building.=—The development of the art of bridge-building seems to have lagged somewhat in the prehistoric period. The use of rafts and boats prevented the need of bridges for crossing streams from being pressing. It is not improbable that some small and crude pile or other timber structures of short spans were employed, but no remains of this class of construction have been found. Large quantities of timber and much of an excellent quality were used in the construction of buildings. That much is known, but there is practically no evidence leading to the belief that timber bridges of any magnitude were used by prehistoric people. It is highly probable that single-timber-beam crossings of small streams were used, but that must be considered the limit of ancient bridging until other evidence than that now available is found.

=10. Ancient Brick-making.=—It has already been seen that stone as a building material has been used since the most ancient periods, and the use of brick goes back almost as far. Fortunately it was frequently a custom of the ancient brick-makers to stamp proprietary marks upon their bricks, and we know by these marks that bricks were made in the Chaldean regions certainly from 3000 to 4000 years before the Christian era. In Egypt also the manufacture of brick dates back nearly or quite as far. Some of these Chaldean bricks, as well as those in other parts of the ancient world, were of poor quality, readily destroyed by water or even a heavy storm of rain when driving upon them. Other bricks, however, were manufactured of good quality of material and by such methods as to produce results which compare favorably with our modern building-bricks. The ruins of cities, at least in Assyria and Chaldea, show that enormous buildings, many of them palaces of kings, were constructed largely of these bricks, although they were elaborately decorated with other material. The walls were heavy, indeed so massive that many of the ruin-mounds are frequently formed almost entirely of the disintegrated brick of poorer quality. These old builders not only executed their work on a

large scale, but did not hesitate to pile up practically an artificial mountain of earth, or other suitable material, on which to construct a palace or temple. The danger of water to these native bricks was so well known and recognized that elaborate and very excellent systems of subsurface drains or sewers were frequently constructed to carry off the storm-water as fast as it fell.

=11. Ancient Arches.=—In the practice of these building operations it became necessary to form many openings and to construct roofs for the sewers or drains, and the arch, both true and false, came to be used in the Euphrates valley, in that of the Nile, and in other portions of the ancient world. Pointed sewer-arches of brick have been found in what is supposed to be the palace of Nimrod on the Tigris River, possibly of the date about 1300 B.C. Excavations at Nippur have revealed a mud-brick pointed arch supposed to date back to possibly 4000 B.C. Also semicircular voussoir arches have been discovered at the ruins of Khorsabad near Nineveh with spans of 12 to 15 feet. These arches are supposed to belong to the reign of Sargon, an Assyrian king who flourished about 705 to 722 B.C. Again, the ancient so-called treasury of Atreus at Mycenæ in Greece, although a dome, exhibits an excellent example of the method of forming the false arch, the date of the construction being probably about 1000 B.C. The main portion of this structure consists of a pointed dome, the diameter of the base being 48 feet and the interior central height 49 feet. A central section shows a beehive shape, as in Fig. 6.

[Illustration: VAULTED DRAIN, KHORSABAD FIG. 4.]

[Illustration: VAULTED DRAINS, KHORSABAD. FIG. 5.]

The exterior approach is between two walls 20 feet apart, the intermediate entrance to the dome or main chamber being a passage 9 feet 6 inches wide at the bottom and 7 feet 10 inches at the top and about 19 feet high. At right angles to the entrance there is a chamber 27 feet by 20 feet cut into the adjacent rock, entered through a doorway about 4 feet 6 inches wide and 9 feet 6 inches high. Both the main entrance to the dome and the doorway to the adjacent chamber are covered or roofed with large flat lintel-stones, over which are the triangular relieving (false) arches, so common in ancient construction, by which the lintels are relieved of load, the triangular openings being closed by single, great upright flat stones. There are a considerable number of these in Greece. The stone used is a “hard and beautiful breccia” from the neighboring hills and Mount Eubora near by. The courses of stone are about two feet thick and closely fitted without cement.

[Illustration: FIG. 6.—Plan and Section of the Treasury of Atreus at Mycenæ.]

1. Plan of the Treasury of Atreus: _A_, rock-cut chamber, probably a tomb; _B_, doorway; _C_, approach.

2. Section of the above: _B_, doorway; _C_, approach filled up with earth; _D_, slope of the ground; _E_, wall on north side of approach; _F_, lintel stone, weight 133 tons; _G_, door to rock-cut chamber.

The great majority, or perhaps all, of the Assyrian true arches, so far discovered, are formed of wedge-shaped bricks, most of them being semicircular, although some are pointed, the span being not over about 15 feet. The most of the arches found at Nineveh and Babylon belong to a period reaching possibly from 1300 to 800 B.C., but some of the Egyptian arches are still older. Egyptians, Assyrians, Greeks, and other ancient people used false arches formed by projecting each horizontal course of stones or bricks over that below it on either side of an opening. The repetition of this procedure at last brings both sides of the opening together at the top of the arch, and they are surmounted at that point with a single flat stone, brick, or tile. It has been supposed by some that these false arches, whose sides may be formed either straight or curved, exhibit the oldest form of the arch, and that the true arch with its ring or rings of wedge-shaped voussoirs was a subsequent development. It is possible that this is true, but the complete proof certainly is lacking. In Egypt and Chaldea both styles of arches were used concurrently, and it is probably impossible to determine which preceded the other. Again, some engineers have contended that two flat slabs of stone leaning against each other, each inclined like the rafters of a roof, was the original form of the arch, as found in the pyramids of Egypt; but it is probable that the true arch was used in Chaldea prior to the time of the pyramids. Indeed crude arches of brick have been found at Thebes in Egypt dating back possibly to 2500 B.C., or still earlier. Aside from that, however, such an arrangement of two stones is not an arch at all, either true or false. The arrangement is simply a combination of two beams. A condition of stress characteristic of that in the true arch is lacking.

The ancient character of the engineering works whose ruins are found in Chaldea and Assyria is shown by the simple facts that Babylon was destroyed about the year 690 B.C. and Nineveh about the year 606 B.C.

CHAPTER II.

=12. The Beginnings of Engineering Works of Record.=—In a later period of the world's history we reach a stage in the development of engineering works of which we have both records and remains in such well-defined shape that the characteristics of the profession may be realized in a definite manner. This is particularly true of the civil-engineering works of the Romans. In their sturdy and unyielding character, with their limitless energy and resolution, the conditions requisite for the execution of engineering works of great magnitude are found. An effeminate or generally æsthetic nation like the Greeks would furnish but indifferent opportunity for the inception and development of great engineering works, but the resolute and vigorous Roman nation offered precisely the conditions needed. They appreciated among other things the absolute necessity of the freest possible communication with the countries which they conquered and made part of their own empire. They recognized water transportation as the most economical and effective, and used it wherever possible. They also realized the advantages of roads of the highest degree of solidity and excellence. No other roads have ever been constructed so direct, so solid, and so admirably adapted to their purposes as those built by the Romans. They virtually ignored all obstacles and built their highways in the most direct line practicable, making deep cuts and fills with apparently little regard for those features which we consider obstacles of sufficient magnitude to be avoided. They regarded this system of land communication so highly that they made it radiate from the Golden Mile-stone in the Roman Forum. The point from which radiated these roads was therefore in the very centre of Roman life and authority, and it fitly indicated the importance which the Roman government gave to the system of communication that bound together with the strongest bonds all parts of the republic and of the empire.

The design and construction of these roads must have been a matter to which their constructors gave the most careful attention and study. They were works involving principles deduced from the most careful thought and extended experience. There were incorporated in them the most effective materials of construction then known, and it was evidently the purpose of their constructors that they should possess indefinite endurance. The existence of some of them at the present time, with no other attention given to them than required for ordinary maintenance, demonstrates that the confidence of the builders was not misplaced.

[Illustration: Street Fountain and Watering-trough in Pompeii. Called the Fountain of Plenty, from the figure with Horn of Plenty on the perforated upright post.]

=13. The Appian Way and other Roman Roads.=—Probably the oldest and most celebrated of these old Roman roads is the Appian Way. It was the most substantially built, and the breadth of roadway varied from 14 to 18 feet exclusive of the footwalks. Statius called it the Queen of Roads. It was begun by Appius Claudius Cæcus, 312 years before the Christian era. He carried its construction from the Roman gate called Porta Capena to Capua, but it was not entirely completed till about the year 30 B.C. Its total length was three hundred and fifty miles, and it formed a perfect highway from Rome to Brundisium, an important port on what may be called the southeastern point of Italy. It was built in such an enduring manner that it appears to have been in perfect repair as late as 500 to 565 A.D.

The plan of construction of these roads was so varied as to suit local conditions, but only as required by sound engineering judgment. They wisely employed local materials wherever possible, but did not hesitate to transport proper material from distant points wherever necessary. This seemed to be one of their fundamental principles of road construction. In this respect the old Romans exhibited more engineering and business wisdom than some of the American states in the beginnings of improved road construction in this country. An examination of the remains of some Roman roads now existing appears to indicate that in earth the bottom of the requisite excavation was first suitably compacted, apparently by ramming, although rollers may have been used. On this compacted subgrade were laid two or three courses of flat stones on their beds and generally in mortar. The second layer placed on the preceding was rubble masonry of small stones or of coarse concrete. On the latter was placed the third layer of finer concrete. The fourth or surface course, consisting of close and nicely jointed polygonal blocks, was then put in place, and formed an excellent unyielding pavement. This resulted in a most substantial roadway, sometimes exceeding 3 feet in total thickness. It is difficult to conceive of a more substantial and enduring type of road construction. The two lower layers were omitted when the road was constructed in rock. Obviously the finer concrete constituting the second layer from the top surface was a binder between the pavement surface and the foundation of the roadway structure.

The paved part of a great road was usually about 16 feet in width, and raised stone causeways or walls separated it from an unpaved way on each side having half the width of the main or paved portion. This seemed to be the type of the great or main Roman roads. Other highways of less important character were constructed of inferior materials, earth or clay sometimes being used instead of mortar; but in such cases greater crowning was employed, and the road was more elevated, possibly for better drainage. Then, as now, adequate drainage was considered one of the first features of good road design. City streets were paved with the nicely jointed polygonal blocks to which reference has already been made, while the footways were paved with rectangular

slabs much like our modern sidewalks.

[Illustration: EXAMPLE OF EARLY BASALT ROAD.

BY THE TEMPLE OF SATURN ON THE CLIVUS CAPITOLINUS.

FIG. 7.]

The smooth polygonal pavements of the old Romans put to the keenest shame the barbarous cobblestone street surfaces with which the people of American cities have been and are still so tortured.

The beneficial influence of these old Roman highways has extended down even to the present time in France, where some of them were built. The unnecessarily elaborate construction has not been followed, but the recognition of the public benefits of excellent roads has been maintained. The lower course of the foundation-stones apparently began to be set on edge toward the latter part of the eighteenth century, the French engineer Tresaguet having adopted that practice in 1764. At the same time he reduced the thickness of the upper layers. His methods were but modifications of the old Roman system, and they prevailed in France until the influence of the English engineers Macadam and Telford began to be felt.

=14. Natural Advantages of Rome in Structural Stones.=—Although the ancient Romans were born engineers, possessing the mental qualities and sturdy character requisite for the analytic treatment and execution of engineering problems, it is doubtful whether they would have attained to such an advanced position in structural matters had not the city of Rome been so favorably located.

The geological character of the great Roman plain and the Roman hills certainly contributed most materially to the early development of some of the most prominent of the Roman engineering works. The plain surrounding the city of Rome is composed largely of alluvial and sandy deposits, or of the emissions of neighboring volcanoes, of which the Alban Hills form a group. While these and other volcanic hills in the vicinity are, and have been for a long period, quiescent, they were formerly in a very active state. The scoriæ, or matter emitted in volcanic eruptions, is found there in all possible degrees of coherence or solidity, from pulverulent masses to hard rock. The characteristic Roman material called tufa is a mixture of volcanic ash and sand, loose and friable, as dropped from the eruptions in large quantities or again compressed into masses with all degrees of hardness. The hard varieties of yellow or brown tufa form building material much used, although a considerable percentage of it would not be considered fit building material for structures of even moderate height at the present time. The most of it weathers easily, but forms a fairly good building-stone when protected by a coating of plaster or stucco.

Another class of building-stones found at or in the vicinity of Rome is the so-called “peperino,” consisting chiefly of two varieties of conglomerate of ash, gravel, broken pieces of lava, and pieces of limestone, some possessing good weathering qualities, while others do not. Ancient quarries of these stones exist whence millions of cubic yards have been removed, and are still being worked. The better varieties of “peperino” possess good resisting qualities, and were much used in those portions of masonry construction where high resistance was needed, as in the ring-stones of arches, heavily loaded points of foundations, and other similar situations.

Some of the prehistoric masonry remains of the Romans show that their earliest constructors appreciated intelligently the qualities of this stone for portions of works where the duty was most severe.

Lava from the extinct volcanoes of the Alban Hills called “silex” was used for paving roads and for making concrete. It was hard and of gray color. At times considerable quantities of this stone were employed. A species of pure limestone called “travertine,” of a creamy white color, was quarried at Tibur or Tivoli, and began to be used about the second century B.C. Vitruvius speaks of its having good weathering qualities, but naturally it is easily calcined. Its structure is crystalline, and it is strong in consequence of that quality only when it is laid on its bed.

=15. Pozzuolana Hydraulic Cement.=—The most valuable of all building materials of old Rome was the “pozzuolana,” as it furnished the basis of a strong, enduring, and economic concrete, and permitted almost an indefinite development of masonry construction. Had there not been at Rome the materials ready at hand to be manufactured into an excellent cementing product, it is highly probable that neither the structural advance nor the commercial supremacy of the Roman people could have been attained. It is at least certain that the majority of the great masonry works constructed by the Romans could not have been built without the hydraulic cementing material produced with so little difficulty and in such large quantities from the volcanic earth called pozzuolana.

The name is believed to have its origin from the large masses of this material at Pozzuoli near Naples. Great beds are also found at and near Rome. The earliest date of its use cannot be determined, but it has given that strong and durable character to Roman concrete which has enabled Roman masonry to stand throughout centuries, to the admiration of engineers.

It is a volcanic ash, generally pulverulent, of a reddish color, but differs somewhat in appearance and texture according to the locality from which it is taken. It consists chiefly of silicate of alumina, but contains a little oxide of iron, alkali, and possibly other components. The Romans therefore pulverized the pozzuolana and mixed it with lime to make hydraulic cement. This in turn was mixed with sand and gravel and broken stone to form mortar and concrete, and that process is carried on to this day. The concrete was hand-mixed, and treated about as it is at present. After having been well mixed the Romans frequently deposited it in layers of 6 to 9 or 10 inches thick, and subjected it to ramming. In connection with this matter of mortar and concrete production, Vitruvius observes that pit-sand is preferable to either sea or river sand.

=16. Roman Bricks and Masonry.=—The Romans produced bricks both by sun-baking and by burning, although there are now remaining apparently no specimens of the former in Rome. Bricks were used very largely for facing purposes, such as a veneer for concrete work. The failure to recognize this fact has led some investigators and writers into error. As matter of fact bricks were used as a covering for concrete work, the latter performing all the structural functions.

The old Roman aqueducts were frequently lined with concrete, made of a mixture of pozzuolana, lime, and crushed (pounded) bricks or potsherds. The same material was also used for floors under the fine mortar in which the mosaics were imbedded.

Marble came into use in Rome about 100 B.C., from Luna, near modern Carrara, Mt. Hymettus, and Mt. Pentelicus, near Athens and the Isle of Paros, nearly all being for sculpture purposes. Colored and structural marbles were brought from quarries in various parts of Italy, Greece, Phrygia, Egypt, near Thebes (oriental alabaster or “onyx”), Arabia, and near Damascus.

From the latter part of the first century B.C. the hard building-stones like granites and basalts were brought to Rome in large quantities. Most of the granites came from Philæ on the Nile. The basalts came both from Lacedæmonia and Egypt. Both emery (from the island of Naxos in the Ægean Sea) and diamond-dust drills were used in quarrying or working these stones. Ships among the largest, if not the largest, of those days, were built to transport obelisks and other large monoliths.

The quality of ancient Roman mortar varies considerably as it is now found. That of the first and second centuries is remarkably hard, and made with red pozzuolana. In the third century it began to be inferior in quality, brown pozzuolana sometimes being used. The reason for this difference in quality cannot be confidently assigned. The deterioration noted in the third century work may be due to the introduction of bad materials, or to the wrong manipulation of material intrinsically good, or it is not unlikely the deterioration is due to a combination of these two influences. The use of mortar indicates a class of early construction; it is found in the Servian wall on the Aventine, of date 700 B.C., or possibly earlier.

[Illustration: Dovetail Wooden Tenon. Wooden Dowel. FIG. 8.]

Under the empire (27 B.C. to A.D. 475) large blocks of tufa, limestone (travertine), or marble were set with very close joints, with either no mortar or, if any, as thin as paper; end, top, and bottom clamps of iron were used to bond such stones together. It was also customary, in laying such large, nicely finished blocks of stone without mortar, to use double dovetailed wooden ties, or, as in the case of columns, a continuous central dowel of wood, as shown in the figures.

The joints were frequently so close as to give the impression that the stones might have been fitted by grinding together. In rectangular dimension stonework (ashlar) great care was taken, as at present, to secure a good bond by the use of judiciously proportioned headers and stretchers. Foundation courses were made thicker than the body of the superincumbent wall, apparently to distribute foundation weights precisely as done at present. Weaker stone was used in thicker portions of walls, and strong stone in thinner portions. Also at points of concentrated loading, piers or columns of strong stone are found built into the bodies of walls of softer or weaker stone. Quarry chips, broken lava, broken bricks, or other suitable refuse fragments were used for concrete in the interest of economy, the broken material always being so chosen as to possess a sharp surface to which the cement would attach itself in the strongest possible bond.

At the quarries where the stones were cut the latter were marked apparently to identify their places in the complete structure, or for other purposes. The remains of the quarries themselves as seen at present are remarkable both for their enormous extent and for the system on which the quarrying was conducted. It appears that the systems employed were admirably adapted to the character of the stone worked, and that the quarrying operations were executed as efficiently and with as sound engineering judgment as

those employed in great modern quarries.

=17. Roman Building Laws.=—So much depended upon the excellence of the building in Rome, and upon the materials and methods employed, that building laws or municipal regulations were enacted in the ancient city, prescribing kind and quality of material, thickness of walls, maximum height of buildings, minimum width of streets, and many other provisions quite similar to those enacted in our modern cities. The differences appear to arise from the different local conditions to be dealt with, rather than from any failure on the part of the old Romans to reach an adequate conception of the general plans suitable for the masses of buildings in a great city. Prior to the great fire A.D. 64 in Nero's reign, an act prescribing fire-proof exterior coverings of buildings was under consideration, and subsequently to that conflagration it was enacted into law. Many of the city roads or streets were paved with closely fitting irregular polygonal blocks of basalt, laid on concrete foundations, and with limestone (travertine) curbs and gutters, producing an effect not unlike our modern streets.

=18. Old Roman Walls.=—In no class of works did the ancient Romans show greater engineering skill or development than in the massive masonry structures that were built not only in and about the city of Rome, but also in distant provinces under Roman jurisdiction. Among the home structures various walls, constituting strong defences against the attacks of enemies, stand in particular prominence. Some of these great structures had their origin prior even to historic times. The so-called "Wall of Romulus," around the famous Roma Quadrata of the Palentine, is among the latter. It is supposed by many that this wall formed the primitive circuit of the legendary city of Romulus. That, however, is an archæological and not an engineering question, and, whatever its correct answer may be, the wall itself is a great engineering work; it demonstrates that the early Romans, whatever may have been their origin, had attained no little skill in quarrying and in the building of dry masonry, no mortar being used in this ancient wall. Portions of it 40 feet high and 10 feet thick at bottom, built against a rocky hill, are still standing. The courses are 22 to 24 inches thick, and they are laid as alternate headers and stretchers; the lengths of the blocks being 3 to 5 feet, and the width from 19 to 22 inches. The ends of the blocks are carefully worked and true, as are the vertical joints in much of the wall, although some of the latter, on the other hand, are left as much as 2 inches open.

Civil engineers, who are familiar with the difficulties frequently experienced in laying up dry walls of considerable height, as evidenced by many instances of failure probably within the knowledge of every experienced engineer, will realize that this great dry masonry structure must have been put in place by men of no little engineering capacity. The rock is soft tufa, and marks on the blocks indicate that chisels from ¼ to ¾ inch in width were used, as well as sharp-pointed picks. In all cases the faces of the blocks were left undressed, i.e., in modern terms they were "quarry-faced."

=19. The Servian Wall.=—Later in the history of Rome the great Servian Wall, built chiefly by Servius Tullius to enclose the seven hills of Rome, occupies a most prominent position as an engineering work. Part of the wall, all of which belongs to the regal period (753 to 509 B.C.), is supposed to be earlier than Servius, and may have been planned and executed by Tarquinius Priscus. A part only of the stones of this wall were laid in cement mortar, and concrete was used, to some extent at least, in its foundation and backing. The presence of cement mortar in this structure differentiates it radically from the wall of Romulus. Probably the discovery of pozzuolana cement, and the fabrication of mortar and concrete from it, had been made in the intervening period between the two constructions. Tufa, usually the softer varieties but of varying degrees of hardness, was mostly used in this wall, and the blocks were placed, as in the previous instance, as alternate headers and stretchers in courses about two feet thick. Portions of the wall 45 feet high and about 12 feet thick have been uncovered. At points it was pierced with arched openings of 11 feet 5 inches span, possibly as embrasures for catapults or other engines of war. The upper parts of these openings are circular arches with the usual wedge-like ring-stones. The voussoirs were cut from peperino stone. This wall, like that of Romulus, was constructed as a military work of defence, and at some points it was built up from the bottom of a wide foss 30 feet deep. At such places it was counterforted or buttressed, a portion of wall 11 feet 6 inches long being found between two counterforts, each of the latter being 9 feet wide and projecting 7 feet 9 inches out from the wall.

[Illustration: FIG. 9.—Part of Servian Wall on Aventine.]

[Illustration: FIG. 10.—Wall and Agger of Servius.]

=20. Old Roman Sewers.=—It is demonstrable by the writings of Vitruvius and others that the old Romans, or at any rate the better educated of them, possessed a correct general idea of some portions of the science of Sanitary Engineering, so far as anything of the nature of science could then be known. Their sanitary views were certainly abreast of the scientific knowledge of that early day. The existence of the "cloacæ," or great sewers, of the ancient city of Rome showed that its people, or at least its rulers, not only

appreciated the value of draining and sewering their city, but also that they knew how to secure the construction of efficient and enduring sewers or drains. It has been stated, and it is probably true, that this system of cloacæ, or sewers, was so complete that every street of the ancient city was drained through its members into the Tiber. They were undoubtedly the result of a gradual growth in sewer construction and did not spring at once into existence, but they date back certainly to the beginning of the period of the kings (753 B.C.). The famous Cloaca Maxima, as great as any sewer in the system, and certainly the most noted, is still in use, much of it being in good order. The mouth of the latter where it discharges into the Tiber is 11 feet wide and 12 feet high, constituting a large arch opening with three rings of voussoirs of peperino stone. Many other sewers of this system are also built with arch tops of the same stone, with neatly cut and closely fitting voussoirs. We do not find, unfortunately, any detailed accounts of the procedures involved in the design of these sewers, yet it is altogether probable that the old Roman civil engineers formed the cross-sections, grades, and other physical features of their sewer system by rational processes, although they would doubtless appear crude and elementary at the present time. It would not be strange if they made many failures in the course of their structural experiences, but they certainly left in the old Roman sewers examples of enduring work of its kind.

Some portions of this ancient sewer system are built with tops that are not true arches, and it is not impossible that they antedate the regal period. These tops are false arches formed of horizontal courses of tufa or peperino, each projecting over that below until the two sides thus formed meet at the top. The outline of the crowns of such sewers may therefore be triangular, curved, or polygonal; they were usually triangular. Smaller drains forming feeders to the larger members of the system were formed with tops composed of two flat stones laid with equal inclination to a vertical line so as to lean against each other at their upper edges and over the axis of the sewer. This method of forming the tops of the drains by two inclined flat stones was a crude but effective way of accomplishing the desired purpose.

The main members of this great sewer system seem to have followed the meandering courses of small rivers or streams, constituting the natural drainage-courses of the site of the city. The Cloaca Maxima has an exceedingly crooked course and it, along with others, was probably first formed by walling up the sides of a stream and subsequently closing in the top. Modern engineers know that such an alignment for a sewer is viciously bad, and while this complicated system of drains is admirably constructed in many ways for its date, it cannot be considered a perfect piece of engineering work in the light of present engineering knowledge. It is probable that the walling in of the sides of the original streams began to be done in Rome at least as early as the advent of the Tarquins, possibly as early as 800 B.C. or earlier.

We know little about the original outfalls or points of discharge into the Tiber, except that, as previously stated, these points were made through the massive quay-walls constructed during the period of the kings along both shores of the Tiber, probably largely for defence as originally built. The discharge of the old Roman sewers through the face of this quay-wall and into the river is precisely the manner in which the sewers of New York City in many places are discharged into the North, East, and Harlem rivers.

The Cloaca Maxima is not the only great ancient sewer thus far discovered. There are at least two others equal to it, and some of the single stones with which they are built contain as much as 45 cubic feet each. These cloacæ were not mere sewers; indeed they were more drains than sewers, for they carried off flood-waters and the natural drainage as well as the sewerage. They were therefore combined sewers and drains closely akin to the sewers of our “combined” systems. The openings into them were made along the streets of Rome and in public buildings or some other public places. There is no evidence that they were ventilated except through these openings, and from each noxious gases were constantly rising to be taken into the lungs of the passers-by. It is a rather curious as well as important fact that so far as excavations have been made there is practically no evidence that a private residence in Rome was connected with the sewers. The “latrines” were generally located adjacent to the Roman kitchens and discharged into the cloacæ.

=21. Early Roman Bridges.=—The early Romans were excellent bridge-builders as well as constructors in other lines of engineering work. Although the ancient city was first located on the left bank of the Tiber, apparently it was but a comparatively short time before the need of means for readily crossing from bank to bank was felt. The capacity of the Roman engineers was equal to the demands of the occasion, and it is now known that seven or eight ancient bridges connected the two shores of the river Tiber. The oldest bridge is that known as Pons Sublicius. No iron was used in its construction, as bronze was the chief metal employed in that early day. The structure was probably all of timber except possibly the abutments and the piers. A French engineer, Colonel Emy, has exhibited in his “Traité de l’Art de la Charpenterie” a plan of this structure restored as an all-timber bridge with pile foundations. Lanciani, on the other hand, believes that the abutments and piers must have been of masonry. The masonry structures, however, known to exist at a later day may have been parts of the work of rebuilding after the two destructions by floods. The date of its construction is not known, but tradition places it in the time of Ancus Marcius. This may or may not be

correct. A flood destroyed the bridge in 23 B.C., and again in the time of Antoninus Pius, but on both occasions it was rebuilt. The structure has long since disappeared. The piers only remained for a number of centuries, and the last traces of them were removed in 1877 in order to clear the bed of the river.

Fig. 11 shows Colonel Emy's restoration of the plan for the pile bridge which Julius Cæsar built across the Rhine in ten days for military purposes. This plan may or may not include accurate features of the structure, but it is certain that such a timber bridge was built, and well preserved pieces of the piles have been taken from under water at the site little the worse for wear after two thousand years of submersion.

The censor Ælius Scaurus built a masonry arch across the Tiber about a mile and a half from Rome in the year 100 B.C. This bridge is now known as the Ponte Molle, and some parts of the original structure are supposed to be included in it, having been retained in the repeated alterations. The arches vary in span from 51 to 79 feet, and the width of the structure is a little less than 29 feet.

In or about the year 104 A.D. the emperor Trajan constructed what is supposed to be a wooden arch bridge with masonry piers across the Danube just below the rapids of the Iron Gate.

[Illustration: Cross-section at Pier.]

[Illustration: Plan at Pier.

FIG. 11.—Bridge thrown across the Rhine by Julius Cæsar.]

A _bas relief_ on the Trajan Column at Rome exhibits the timber arches, but fails to give the span lengths, which have been the subject of much controversy, some supposing them to have been as much as 170 feet.

The ancient Pons Fabricius, now known as Ponte Quattiro Capi, still exists, and it is the only one which remains intact after an expiration of nearly two thousand years. It has three arches, the fourth being concealed by the modern embankment at one end; a small arch pierces the pier between the other two arches. This structure is divided into two parts by the island of Æsculapius. It is known that a wooden bridge must have joined that island with the left bank of the Tiber as early as 192 B.C., and a similar structure on the other side of the island is supposed to have completed the structure. While Lucius Fabricius was Commissioner of Roads in the year 62 B.C. he reconstructed the first-named portion into a masonry structure of arches. An engraved inscription below the parapets shows that the work was duly and satisfactorily completed, and further that it was the custom to require the constructors or builders of bridges to guarantee their work for the period of forty years. Possession of the last deposit, made in advance as a guarantee of the satisfactory fulfilment of the contract, could not be regained until the forty-first year after completion.

[Illustration: FIG. 12.—Trajan's Bridge.]

The Pons Cestius is a bridge since known as the Pons Gratianus and Ponte di S. Bartolomeo. Its first construction is supposed to have been completed in or about 46 B.C., and it was rebuilt for the first time in A.D. 365. A third restoration took place in the eleventh century. The modern reconstruction in 1886-89 was so complete that only the middle arch remains as an ancient portion of the structure. The island divides the bridge into two parts, the Ship of Æsculapius lying between the two, but it is not known when or by whom the island was turned into that form.

Another old Roman bridge, of which but a small portion is now standing, is Pons Æmilius, the piers of which were founded in 181 B.C., but the arches were added and the bridge completed only in 143 B.C. It was badly placed, so that the current of the river in times of high water exerted a heavy pressure upon the piers, and in consequence it was at least four times carried away by floods, the first time in the year A.D. 280.

The discovery of what appears to be a row of three or four ruins of piers nearly 340 feet up-stream from the Ponte Sisto seems to indicate that a bridge was once located at that point, although little or nothing is known of it as a bridge structure. Some suppose it to be the bridge of Agrippa.

The most historical of all the old Roman bridges is that which was called Pons Ælius, now known as Ponte S. Angelo, built by Hadrian A.D. 136. Before the reconstruction of the bridge in 1892 six masonry arches were visible, and the discovery of two more since that date makes a total of eight, of which it is supposed that only three were needed in a dry season. The pavement of the approach to this bridge as it existed in 1892 was the ancient roadway surface. Its condition at that time was an evidence of the

substantial character of the old Roman pavement.

Below the latter bridge remains of another can be seen at low water. It is supposed that this structure was the work of Nero, although its name is not known.

The modern Ponte Sisto is a reconstruction of the old Pons Valentinianus or bridge of Valentinian I. The latter was an old Roman bridge, and it was regarded as one of the most impressive of all the structures crossing the river. It was rebuilt in A.D. 366-67.

The most of these bridges were built of masonry and are of the usual substantial type characteristic of the early Romans. They were ornamented by masonry features in the main portions and by ornate balustrades along either side of the roadway and sidewalks. The roadway pavements were of the usual irregular polygonal old Roman type, the sidewalk surfaces being composed of the large slabs or stones commonly used in the early days of Rome for that purpose.

=22. Bridge of Alcantara.=—Among the old Roman bridges should be mentioned that constructed at Alcantara in Spain, supposedly by Trajan, about A.D. 105. It is 670 feet long and its greatest height is 210 feet. One of its spans is partially destroyed. The structure is built of blocks of stone without cementing material. In this case the number of arches is even, there being six in all, the central two having larger spans than those which flank them. It is a bridge of no little impressiveness and beauty and is a most successful design.

=23. Military Bridges of the Romans.=—In the old Roman military expeditions the art of constructing temporary timber structures along lines of communication was well known and practised with a high degree of ability. Just what system of construction was employed cannot be determined, but piles were constantly used. At least some of these timber military bridges, and possibly all, were constructed with comparatively short spans, the trusses being composed of such braces and beams as might be put in place between bents of piles. As already observed, some of the sticks of these bridges have been found in the beds of German rivers, and at other places, perfectly preserved after an immersion of about two thousand years. These instances furnish conclusive evidence of the enduring qualities of timber always saturated with water.

=24. The Roman Arch.=—The Romans developed the semicircular arch to a high degree of excellence, and used it most extensively in many sewers, roads, and aqueducts. While the aqueduct spans were usually made with a length of about 18 or 20 feet, they built arches with span lengths as much as 120 feet or more, comparing favorably with our modern arch-bridge work. They seldom used any other curve for their arches than the circular, and when they built bridges an odd number of spans was usually employed, with the central opening the largest, possibly in obedience to the well-known esthetic law that an odd number of openings is more agreeable to the eye than an even number. Apparently they were apprehensive of the safety of the piers from which their arches sprang, and it was not an uncommon rule to make the thickness of the piers one third of the clear span. Nearly one fourth of the entire length of the structure would thus be occupied by the pier thicknesses. Although the use of mortar, both lime and cement, early came into use with the Romans, they usually laid up the ring-stones of their arches dry, i.e., with out the interposition of mortar joints.

CHAPTER III.

=25. The Roman Water-supply.=—There is no stronger evidence of engineering development in ancient Rome, nor of the advanced state of civilization which characterized its people, than its famous system of water-supply, which was remarkable both for the volume of water daily supplied to the city and for the extensive aqueducts, many of whose ruins still stand, as impressive monuments of the vast public works completed by the Romans. These ruins, and those of many other works, would of themselves assure us of the elaborate system of supply, but fortunately there has been preserved a most admirable description of it, the laws regulating consumption, the manner of administering the water department of the government of the ancient city, and much other collateral information of a most interesting character. In the work entitled, in English, “The Two Books on the Water-supply of the City of Rome,” by (Sextus) Julius Frontinus, an eminent old Roman citizen, who, besides having filled the office of water commissioner[1] of the city, was governor of Britain and three times consul, as well as having enjoyed the dignity of being augur. He may properly be called a Roman engineer, although he evidently was a man of many public affairs, and so esteemed by the emperors who ruled during his time that he accompanied them in various wars as a military man of high rank. He wrote seven books at least, viz., “A Treatise on Surveying,” “Art of War,” “Strategematics,” “Essays on Farming,” “Treatise on Boundaries, Roads, etc.,” “A Work on Roman Colonies,” and his account of the water-works of Rome, entitled “De Aquis.” It is the latter book in which engineers are particularly interested. The translation of this book from the original Latin is made from what is termed the

“Montecassino Manuscript,” an account of which with the translation is given by Mr. Clemens Herschel in his entertaining work, “Frontinus, and the Water-supply of the City of Rome.”

[1] The first permanent water commissioner in Rome was M. Agrippa, son-in-law of Cæsar Augustus, who took office B.C. 34. He was one of the greatest Roman engineers and constructors, if indeed he was not the first in rank.

As near as can be determined Frontinus lived from about A.D. 35 to A.D. 103 or 104. Judging from the offices which Frontinus held and the honors which he enjoyed throughout his life, it would appear that he was a patrician; he was certainly a man of excellent executive capacity, of intellectual vigor and refined taste, and a conscientious public servant. The water-supply of the city was held by the Romans to be one of the most important of all its public works, and its administration during the life of Frontinus was entrusted to what we should call a water commissioner, appointed by the emperor. It was considered to be an office of dignity and honor, and the proper discharge of its responsibilities was a public duty which required a high order of talent, as well as great integrity of character.

=26. The Roman Aqueducts.=—Frontinus states that from the foundation of the city of Rome until 313 B.C., i.e., for a period of 441 years, the only water-supply was that drawn either from the river Tiber or from wells or springs. The veneration of the Romans for springs is a well-known feature of their religious tenets. They were preserved with the greatest care, and hedged about with careful safeguards against irreverent treatment or polluting conditions. Apparently after this date the people of Rome began to feel the need of a public water-supply adequate to meet the requirements of a great city. At any rate, in the year 313 B.C. the first aqueduct, called the Appia, for bringing public water into the city of Rome was attempted by Censors Appius Claudius, Crassus, and C. Plautius, the former having constructed the aqueduct, and the latter having found the springs. Appius must have been an engineer of no mean capacity, for it was he who constructed the first portion of the Appian Way. The origin of this water-supply is some springs about 10 miles from Rome, and they may now be seen at the bottom of stone quarries in the valley of the Anio River. This aqueduct, Aqua Appia, is mostly an underground waterway, only about 300 feet of it being carried on masonry arches. At the point where it enters the city it was over 50 feet below the surface; its clear cross-section is given as 2½ feet wide by 5 feet high. The elevation of its water surface in Rome was probably under 60 feet above sea-level.

[Illustration: Claudia, of dimension stone, and Anio Novus, of brick and concrete, on top of it.]

=27. Anio Vetus.=—The next aqueduct built for the water-supply of Rome was called Anio Vetus. It was built 272-269 B.C., and is about 43 miles long; it took its water from the river Anio. About 1100 feet of its length was carried above ground on an artificial structure. It also was a low-level aqueduct, the elevation at which it delivered water at Rome being about 150 feet above sea-level. It was built of heavy blocks of masonry, laid in cement, and the cross-section of its channel was about 3.7 feet wide by 8 feet high. In the year 144 B.C. the Roman senate made an appropriation equal to about $400,000 of our money to repair the two aqueducts already constructed, and to construct a new one called Aqua Marcia, to deliver water to the city at an elevation of about 195 feet above sea-level. This aqueduct was finished 140 B.C.; it is nearly 58 miles long, and carried water of most excellent quality through a channel which, at the head of the aqueduct, was 5■ feet wide by 8³/■■ feet high, but farther down the structure was reduced to 3 feet wide by 5■/■■ feet high. The excellent water of these springs is used for the present supply of Rome, and is brought in the Aqua Pia, built in 1869, as a reconstruction of the old Aqua Marcia. This aqueduct, like its two predecessors, is built of dimension stone, 18 inches by 18 inches by 42 inches, or larger, laid in cement; but concrete and brick were used in the later aqueducts, with the exception of Claudia.

=28. Tepula.=—The aqueduct called Aqua Tepula, about 11 miles in length, and completed 125 B.C., was constructed to bring into the city of Rome a slightly warm water from the volcanic springs situated on the hill called Monte Albani (Alban Hills) southeast of Rome. The temperature of these springs is about 63° Fahr. In the year B.C. 33 Agrippa caused the water from some springs high up the same valley to be brought in over the aqueduct Aqua Julia, 14 miles long. This latter water was considerably colder than that of the Tepula Springs. The two waters were united before reaching Rome and allowed to flow together far enough to be thoroughly mixed. They were then divided and carried into Rome in two conduits. The volume of water carried in the Aqua Julia was about three times that taken from the Tepula Springs, the cross-section of the latter being only 2.7 feet wide by 3.3 feet high, while that of Julia was 2.3 feet by 4.6 feet. The water from Aqua Julia entered Rome at an elevation of about 212 feet above sea-level, and that from Aqua Tepula about 11 feet lower.

=29. Virgo.=—The sixth aqueduct in chronological order was called Virgo, and it was completed 19 B.C. It takes water from springs about 8 miles from Rome and only about 80 feet above sea-level, but the length of the aqueduct is about 13 miles. The delivery of

water in the city by this aqueduct is about 67 feet above that level. The cross-section of this channel is about 1.6 feet wide and 6.6 feet high.

=30. Alsietina.=—The preceding aqueducts are all located on the left or easterly bank of the Tiber, but one early structure was located on the right bank of the Tiber to supply what was called the Trans-Tiberine section of the city, and it was known as Aqua Alsietina. The emperor Augustus had this aqueduct constructed during his reign, and it was finished in the year A.D. 10. Its source is a small lake of the same name with itself, about 20 miles from Rome. The elevation of this lake is about 680 feet above sea-level, while the water was delivered at an elevation of about 55 feet above the same level. The water carried by this aqueduct was of such a poor quality that Frontinus could not “conceive why such a wise prince as Augustus should have brought to Rome such a discreditable and unwholesome water as the Alsietina, unless it was for the use of Naumachia.” The latter was a small artificial lake or pond in which sham naval fights were conducted.

[Illustration:

Sand and Pebble Catch-tanks near Tivoli. Dimension-stone aqueducts of Marcia at either end of the tank built of small stone; _opus incretum_. The arches are chambers of the tanks.]

=31. Claudia.=—The eighth aqueduct described by Frontinus is the Aqua Claudia, built of dimension stone, which he calls a magnificent work on account of the large volume of water which it supplied, its good quality, and the impressive character of considerable portions of the aqueduct itself, between 9 and 10 miles being carried on arches. It was built in 38-52 A.D. and is forty-three miles long. The sources of its supply are found in the valley of the Anio, and consequently it belongs to the system on the left bank of the Tiber. The cross-section of its channel was about 3.3 feet wide by 6.6 feet high. It was a work greatly admired by the Roman people, as is evidenced by the praise “given to it by Roman authors who wrote at that time.” It delivered water at the Palatine 185 feet above sea-level. According to Pliny, the combined cost of it and the Aqua Anio Novus was 55,500,000 sestertii, or nearly $3,000,000. This aqueduct probably belongs to the highest type of Roman hydraulic engineering. It follows closely the location of the Aqua Marcia, although its alignment now includes a cut-off tunnel about 3 miles long, the latter having been constructed about thirty-six years after the aqueduct was opened. Mr. Clemens Herschel observes that the total sum expended for these two aqueducts makes a cost of about $6 per lineal foot for the two. The arches of this aqueduct and those of the Anio Novus have clear spans of 18 to 20 feet, with a thickness at the crown of about 3 feet.

=32. Anio Novus.=—The ninth aqueduct described by Frontinus is called Anio Novus. It was also constructed in the years A.D. 38-52. This aqueduct has a length of about 54 miles and takes its supply from artificial reservoirs constructed by Nero at his country-seat in the valley of the Anio near modern Subiaco. This structure is built of brick masonry lined with concrete. That portion of the Aqua Claudia which is located on the Campagna carries for 7 miles the Anio Novus, and it forms the long line of aqueduct ruins near Roma Vecchia. The upper surface of the arch-ring at the crown forms the bottom of the channel of the aqueduct. The cross-section of the channel of the Anio Novus was 3.3 feet wide by 9 feet high. The elevation of the water in this, as in the Claudia, when it reached the Palatine was about 185 feet above sea-level. The Anio Novus in some respects would seem to be a scarcely less notable work than the Claudia. About 8 miles of its length is carried on arches, some of them reaching a height of about 105 feet from the ground.

=33. Lengths and Dates of Aqueducts.=—These nine aqueducts constituted all those described by Frontinus, as no others were completed prior to his time. Five others were, however, subsequently completed between the years 109 A.D. and 306 A.D., but enough has already been shown in connection with the older structures to show the character of the water-supply of ancient Rome.

The following tabular statement is a part of that given by Mr. F. W. Blackford in “The Journal of the Association of Engineering Societies,” December, 1896. It shows the dates and lengths of the ancient aqueducts of Rome between the years 312 B.C. and 226 A.D., with the length of the arch portions. The list includes those built up to the end of the Empire. It will be observed that the total length of the aqueducts is 346 miles, and that of the arch portions 44 miles. The figures vary a little from those given by Lanciani and others, but they are essentially accurate.

+------------+--------+----------+----------+ | | | Total |Length of | | Name. | Date. |Length in |Arches in | | | B.C. | Miles. | Miles. | +------------+--------+----------+----------+ |Appia | 312 | 11 | Little | |Vetus | 272-264| 43 | ” | |Marcia | 145 | 61 | 12 | |Tepula | 126 | 13 | Little | |Julia | 34 | 15 | 6 | |Virgo | 21 | 14 | Little | | | | | | | | A.D. | | | |Alsietina | 10 | 22 | Little | |Augusta | 10 | 6 | ” | |Claudia | 50 | 46 | 10 | |Anio Novus | 52 | 58 | 9 | |Triana | 109 | 42 | Little | |Alexandrina | 226 | 15 | 7 | | +--------+----------+----------+ | Totals | 346 | 44 | +------------+--------+----------+----------+

=34. Intakes and Settling-basins.=—The preceding brief descriptions of the old Roman aqueducts give but a superficial idea of the real features of those great works and of the system of water-supply of which they were such essential portions. Enough has been shown, however, to demonstrate conclusively that the engineers and constructors of old Rome were men who, on the one hand, possessed a high order of engineering talent and, on the other, ability to put in place great structures whose proportions and physical characteristics have commanded the admiration of engineers and others from the time of their completion to the present day. If a detailed statement were to be made in regard to the water-supply of ancient Rome, it would appear that much care was taken to insure wholesome and potable water. At the intakes of a number of the aqueducts, reservoirs or basins were constructed in which the waters were first received and which acted as settling-basins, so that as much sedimentation as possible might take place. Similar basins (picinæ) were also constructed at different points along the aqueducts for the same purpose and for such other purposes as the preservation of the water in a portion of the aqueduct in case another portion had to be repaired or met with an accident which for the time being might put it out of use. These basins were usually constructed of a number of apartments, the water flowing from one to the other, very much as sewage in some sewage-disposal works flows at the present time through a series of settling-basins. The object of these picinæ was the clearing of the water by sedimentation. Indeed there was in some cases a use of salt in the water to aid in clarifying it. This is an early type of the modern process of clarifying water by chemical precipitation, not the best of potable water practice, but one that is sometimes permissible.

=35. Delivery-tanks.=—The aqueducts brought the water to castellæ or delivery-tanks, i.e., small reservoirs, both inside the city and outside of it, and from these users were obliged by law to take their supplies; that is, for baths, for fountains, for public uses, for irrigation, and for private uses. When Frontinus wrote his “De Aquis” a little less than three tenths of all the water brought to Rome by the aqueducts was used outside of the city. The remainder was distributed in the city from 247 delivery-tanks or small reservoirs, about one sixth of it being consumed by 39 ornamental fountains and 591 water-basins.

=36. Leakage and Lining of Aqueducts.=—These aqueducts were by no means water-tight. Indeed they were subject to serious leakage, and Frontinus shows that forces of laborers were constantly employed in maintaining and repairing them. As has been stated, the older aqueducts were built of dimension stones, while the later were constructed of concrete or bricks and concrete. The channels of these aqueducts, as well as reservoirs and other similar structures, were made as nearly water-tight as possible by lining them with a concrete in which pottery, broken into fine fragments, was mixed with mortar.

[Illustration: Claudia and Anio Novus near Porta Furba. Repairs in brickwork and in a composite of concrete and brickwork.]

=37. Grade of Aqueduct Channels.=—The fall of the water surface in these aqueducts cannot be exactly determined. The levelling-instruments used by the Romans were simple and, as we should regard them, crude, although they served fairly well the purposes to which they were applied. They were not sufficiently accurate to determine closely the slope or grade of the water surface in the aqueduct channels. The deposition of the lime from the water along the water surface on the sides of the channels in many cases would enable that slope to be determined at the present time, but sufficiently careful examinations have not yet been made for that purpose. Lanciani states that the slopes in the Aqua Anio Vetus vary from about one in one thousand to four in one thousand. An examination of the incrustation on the sides of the Aqua Marcia near its intake makes it appear that the slope of the surface was about .06 foot per 100 feet, which would produce a velocity, according to the formula of Darcy, of about 3.3 feet per second. In some aqueducts built in Roman provinces it would appear that slopes have been found ranging from one in six hundred to one in three thousand.

=38. Qualities of Roman Waters.=—The chief characteristic in most of the old Roman waters was their extreme hardness. They range from 11° to 48° of hardness, the latter belonging to the water of the Anio, while the potable waters in this country scarcely reach 5°. The old Romans recognized these characteristics of their waters and, as has been intimated, used the best of them for table purposes, while the less wholesome were employed for fountains, flushing sewers, and other purposes not affected by undesirable qualities. The water from Claudia, for instance, was used for the imperial table. The water from the Aqua Marcia was also of excellent quality, while that brought in by the Aqua Alsietina was probably not used for potable purposes at all.

=39. Combined Aqueducts.=—In several cases a number of aqueduct channels were carried in one aqueduct. A marked instance of this kind was that of Julia, Tepula, and Marcia, all being carried in vertical series in one structure. Numerous instances of this sort occurred.

=40. Property Rights in Roman Waters.=—In reading the two books of Frontinus one will be impressed by the property values which the old Romans created in water rights. The laws of Rome were exceedingly explicit as to the rights of water-users and as to

the manner in which water should be taken from the aqueducts and from the pipes leading from the reservoirs in and about the city. The proper methods for taking the water and using it were carefully set forth, and penalties were prescribed for violations of the laws pertaining to the use of water. There were many abuses in old Rome in the administration of the public water-supply, and one of the most troublesome duties which Frontinus had to perform lay in reforming those abuses and preventing the stealing of water. The unit of use of water (a "quinaria," whose value is not now determinable) was the volume which would flow from an orifice .907 inch in diameter and having an area of about .63 of a square inch. Mr. Herschel shows that in consequence of the failure of the Romans to understand the laws of the discharge of water under varying heads, the quinaria may have ranged from .0143 cubic foot to .0044 cubic foot per second or between even wider limits.

=41. Ajutages and Unit of Measurement.=—Frontinus describes twenty-five ajutages of different diameter, officially approved in connection with the Roman system of public water-supply; but only fifteen of these were actually used in his day. All of these were circular in form, although two others had been used prior to that time. They varied in diameter from .907 to 8.964 English inches and were originally made of lead, but that soft metal lent itself too easily to the efforts of unscrupulous water-users to enlarge them by thinning the metal. In his time they were made of bronze, which was a hard metal and could not be tampered with so as to enlarge its cross-section. The discharge through the smallest of these ajutages was the quinaria, the unit in the scale of water rights. The largest of the above ajutages had a capacity of a little over 97 quinariæ.

This unit (the quinaria) was based wholly on superficial area, and had no relation whatever to the head over the orifice or to the velocity corresponding to that head. Although Frontinus refers in several cases to the fact that the deeper the ajutage is placed below the water surface the greater will be the discharge through it, also to the fact that a channel or pipe of a given area of cross-section will pass more water when the latter flows through it with a high velocity, he and other Roman engineers seem to have failed completely to connect the idea of volume of discharge to the product of area of section by velocity. In the Roman mind of his day, and for perhaps several hundred years after that, the area of the cross-section of the prism of water in motion was the only measure of the volume of discharge. This seems actually preposterous at the present time, and yet, as observed by Mr. Herschel, possibly a majority of people now living have no clearer idea of the volume of water flowing in either a closed or open channel. Existing statutes even respecting water rights bear out this statement, improbable as it may at first sight appear. This early Roman view of the discharge is, however, in some respects inexplicable, for Hero of Alexandria wrote, probably in the period 100-50 B.C., that the section of flow only was not sufficient to determine the quantity of water furnished by a spring. He proceeded to set forth that it was also necessary to know the velocity of the current, and further explained that by forming a reservoir into which a stream would discharge for an hour the flow or discharge of that stream for the same length of time would be equal to the volume of water received by the reservoir. His ideas as to the discharge of a stream of water were apparently as clear as those of a hydraulic engineer of the present time. Indeed the method which he outlines is one which is now used wherever practicable.

It has been a question with some whether Frontinus and other Roman engineers were acquainted with the fact that a flaring or outward ajutage would increase the flow or discharge through the orifice. The evidence seems insufficient to establish completely that degree of knowledge on their part. At the same time, in the CXII chapter of Frontinus' book on the "Water-supply of the City of Rome," he states that in some cases pipes of greater diameter than that of the orifice were improperly attached to legal ajutages. He then states: "As a consequence the water, not being held together for the lawful distance, and being on the contrary forced through the short restricted distance, easily filled the adjoining larger pipe." He was convinced that the use of a pipe with increased diameter under such circumstances would give the user of the water a larger supply than that to which he was entitled, and he was certainly right in at least most cases.

The actual unit orifice through which the unit volume of water called the quinaria was discharged was usually of bronze stamped by a proper official, thus making its use legal for a given amount of water. The Roman engineers understood that such an orifice should be inserted accurately at right angles to the side of the vessel or orifice, and that was the only legal way to make the insertion. Furthermore, the law required that there should be no change in the diameter of the pipe within 50 feet of the orifice. It was well known that a flaring pipe of increased diameter applied immediately at the orifice would largely increase the discharge, and unscrupulous people resorted to that means for increasing the amount of water to be obtained for a given price.

=42. The Stealing of Water.=—It appears also that Frontinus experienced much trouble from clandestine abstraction of water from reservoirs and water-pipes. The administration of the water commissioner's office had been exceedingly corrupt prior to his induction into office, and some of his most troublesome official work arose from his efforts to detect water-thieves, and to guard the supply system from being tapped irregularly or illegally. We occasionally hear of similar instances of water-stealing at the present time, which shows that human nature has not altogether changed since the time of Frontinus.

=43. Aqueduct Alignment and Design of Siphons.=—The alignment of some of the Roman aqueducts followed closely the contours of the hills around the heads of valleys, while others took a more direct line across the valleys on suitable structures, frequently series of arches. Judging from our own point of view it may not be clear at first sight why such extensive masonry constructions were used when the aqueduct could have been kept in excavation by following more closely the topography of the country. There is little doubt that the Romans knew perfectly well what they were about. Indeed it is definitely stated in some of the old Roman writings that the structures were built across valleys for the specific purpose of saving distance which, in most instances at least, meant saving in cost.

These masonry structures, it must be remembered, were built of material immediately at hand. Furthermore, these aqueducts were generally only made of sufficient width for the purpose of carrying water-channels. They were not wide structures. In some cases they were not more than 8 feet or 9 feet wide for a height of nearly 100 feet. The cost of construction was thus largely reduced below that of wide structures.

[Illustration: Old Roman Lead and Terra-cotta Pipe.]

The Romans were perfectly familiar with the construction of inverted siphons. As a matter of fact Vitruvius, in Chapter VII of his Eighth book, describes in detail how they should be designed. His specific descriptions relate to lead pipes, but it is clear from what he states at other points that he considered earthenware pipes equally available. He sets forth how the pipes should be carried down one slope, along the bottom of the valley, and up the other slope, the lowest portion being called the “venter.” He realized the necessity of guarding all elbows in the pipe by using a single piece of stone as a detail for the elbow, a hole being cut in it in each direction in which the adjoining sections of pipe should be inserted, the sections of lead pipe being 10 feet long, and even goes so far as to describe the stand-pipes that should be inserted for the purpose of allowing air to escape. Vitruvius also advises that the water should not only be admitted to inverted siphons in a gradual manner, but that ashes should be thrown into the water when the siphon is first used in order that they may settle into the joints or open places so as to close any existing leaks. Lead pipe siphons, 12 to 18 inches in diameter, with 1 inch thickness of metal under 200 feet head, built in ancient times, have been found at Lyons in France. Also a drain-pipe siphon with masonry reinforcement was built at Alatri in Italy 125 B.C. to carry water under a head of about 340 feet. There are other notable instances of inverted siphons constructed and used during the ancient Roman period, some of them being of lead pipe imbedded in concrete.

CHAPTER IV.

=44. Antiquity of Masonry Aqueducts.=—Masonry aqueducts, either solid or with open arches, were not first constructed by the city of Rome; their origin was much farther back in antiquity than that. The Greeks at least used them before the Roman engineers, and it is not unlikely that the latter drew their original ideas from the former, if indeed they were not instructed by them. Nor during the times of the Romans was the construction of aqueducts confined to Rome. Wherever Roman colonies were created it would appear that vast sums were expended in the construction of aqueducts for the purpose of suitably supplying cities with water. Such constructions are found at many points in Spain, France, and other countries which were in ancient times Roman colonies. It is probable that there are not less than one hundred, and perhaps many more, of such structures in existence at the present time.

=45. Pont du Gard.=—Among the more prominent aqueducts constructed during the old Roman period and outside of Italy were the Pont du Gard at Nismes in the south of France, and those at Segovia and Tarragona in Spain. The Pont du Gard has three tiers of arches with a single channel at the top. The greatest height above the river Gardon is about 180 feet, and the length of the structure along the second tier of arches is 885 feet. The arches in the lowest tier are 51 feet, 63 feet, and 80.5 feet in span, while the arches in the highest tier are uniformly 15 feet 9 inches in span. The thickness of the masonry at the top of the structure from face to face is 11 feet 9 inches, and 20 feet 9 inches at the lower tier of arches, the thickness at the intermediate tier being 15 feet.

The largest arch has a depth of keystone of 5 feet 3 inches, while the other arches of the lower tier have a depth of keystone of 5 feet. The depth of the ring-stones of the small upper arches is 2 feet 7 inches. This structure forms a sort of composite construction, the lower arches constituting four separate arch-rings placed side by side, making a total thickness of 20 feet 9 inches. The intermediate arches consist of three similar series of narrow arches placed side by side, but the masonry of the upper tier is continuous throughout from face to face. The three and four parallel series of arches of the middle and lowest tiers are in no way bonded or connected with each other. There is no cementing material in any of the arch-rings, but cement mortar was used in rubble masonry or concrete around the channel through which the water flowed above the upper tier of small arches. This structure is supposed to have been built between the years 31 B.C. and 14 A.D.

=46. Aqueducts at Segovia, Metz, and Other Places.=—The Segovia aqueduct was built by the emperor Trajan about A.D. 100-115. It is built without mortar, and has 109 arches, but 30 are modern, being reproductions of the old. It has a length of over 2400 feet, and in places its height is about 100 feet. The old Tarragona aqueduct is built with two series of arches, 25 being in the upper series and 11 in the lower. It is 876 feet long and has a maximum height of over 80 feet. At Mayence there are ruins of an aqueduct about 16,000 feet long. In Dacia, Africa, and Greece there are other similar ruins. Near Metz are the remains of a large old Roman aqueduct. It consisted of a single row of arches, and had no features of particular prominence. This latter observation, however, could not be made of one of the bridges in the aqueduct at Antioch. Although the masonry and design of this latter structure were crude, its greatest height is 200 feet, and its length 700 feet. The lower portion of this structure was a solid wall with the exception of two openings, the arches extending in a single row along its upper portion. On the island of Mytilene are the ruins of another old aqueduct about 500 feet long, with a maximum height of about 80 feet.

The building of these remarkable aqueducts was practised at least down to the later periods of the Roman empire, that of Pyrgos, near Constantinople,—built not earlier than the tenth century,—being an excellent example. It consists of two branches at right angles to each other. The greater branch is 670 feet long, and its greatest height 106 feet. There are three tiers of arches, the two upper being of semicircular and the lower of Gothic outline. The number in each tier for a given height is the same, but with an increasing length of span in rising from the lowest to the highest tier. Thus the highest tier of piers is the lightest, relieving the top of the structure of weight. The lowest row of piers is reinforced by counterforts or buttresses. At the top of the structure the width or thickness is 11 feet, but the thickness increases uniformly to 21 feet at the bottom. The smaller branch of the aqueduct is 300 feet long, and was built with twelve semicircular arches.

=47. Tunnels.=—The construction of tunnels, especially in connection with the building of aqueducts, constituting a branch of engineering procedure, was frequently practised by the ancient nations. Large tunnel-works were executed many times by the ancient Greeks and Romans. It would seem that the Greeks were the instructors of the Romans in this line of engineering operations. As early as B.C. 625 we are told that the Greek engineer Eupalinus constructed a tunnel 8 feet broad, 8 feet high, and 4200 feet long, through which was built a channel for carrying water to the city of Athens.

Sixty-five years later a similar work was constructed for the same Grecian city. Indeed it appears that tunnels were constructed in the time of the earliest history of aqueducts built to supply ancient Greek and Roman cities with water.

It is certain that at the beginning of the Christian era tunnelling processes were well known among the Romans. Vitruvius writes, in speaking of the construction of aqueducts, in Chapter VII of the Eighth Book: “If hills intervene between the city wall and spring head, tunnels underground must be made, preserving the fall above assigned; if the ground cut through be sandstone or stone, the channel may be cut therein; but if the soil be earth or gravel, side walls must be built, and an arch turned over, and through this the water may be conducted. The distance between the shafts over the tunnelled part is to be 120 feet.”

The Romans pierced rock in their tunnel-work, not only by chiselling, but sometimes by building fire against the rock so as to heat it as hot as possible. The heated rock was then drenched with cold water, so that it might be cracked and disintegrated to as great an extent as practicable. According to Pliny vinegar was used instead of water in some cases, under the impression that it was more efficacious.

[Illustration: Roman water-pipe made of bored-out blocks of stone.]

One of the methods mentioned by Vitruvius is plainly “the cut and cover” procedure of the present day. In Duruy’s history of Rome a tunnel over three miles long is mentioned on a line of an aqueduct at Antibes in France, as well as another constructed to drain Lake Fucinus in Italy, about A.D. 50. It is there stated that the latter required eleven years’ labor of 30,000 men to build a rock tunnel with a section of 86 to 96 square feet 18,000 feet long.

Lanciani, in his “Ancient Rome,” states that about A.D. 152 a Roman engineer (Nonius Datus) began the construction of a tunnel in Algeria, and after having carefully laid out the axis of the tunnel across the ridge “by surveying, and taking the levels of the mountains,” left the progress of the work in the hands of the contractor and his workmen. After the rather long absence from such a work of four years he was called back by the Roman governor to ascertain why the two opposite sections of the tunnel, as constructed, would not meet, and to take the requisite measures for the completion of the work through which water was to be conducted to Saldæ in a suitable channel. He explains that there should have been no difficulty, and that the failure of the two headings to meet was due to the negligence of the contractor and his assistant, whom he states “had committed blunder upon blunder,” although he writes, “As always happens in these cases, the fault was attributed to the engineer.” He solved the problem

by connecting the two approximately parallel tunnels by a transverse tunnel, so that water was finally brought to the city of Saldæ.

The art of tunnel construction has been one of the most widely practised branches of Civil-Engineering from the times of the ancient Assyrians, Egyptians, Greeks, Romans, and other ancient nations down to the present.

=48. Ostia, the Harbor of Rome.=—The capacity of the ancient Romans to build harbor-works is shown by what they did at Ostia, which was then at the mouth of the Tiber, but is now not less than four miles inland from the present shore line. At the Ostia mouth of the river the present annual average advance seaward is not less than 30 feet, and at the Fiumicino mouth about one third of that amount.

[Illustration: FIG. 13.—Plan of Ostia and Porto.]

The ancient port of Ostia is supposed to have been founded during the reign of the fourth king Ancus Marcius, but it attained its period of greatest importance during the reign of Claudius and Trajanus. At that time the fertile portions of the Campania had been so largely taken up by the country-places of the wealthy Romans that it was no longer possible for the peasantry to cultivate sufficient ground to yield the grain required by the home market of the Romans. Large fleets were consequently engaged in the foreign grain-trade of Rome. The wheat and other grain required in great quantities was grown mostly in Egypt, although Carthage and other countries supplied large amounts. The great fleets occupied in this trade made ancient Ostia their Roman port. At the present time it has no inhabitants, but is a group of complete ruins, with its streets of tombs, baths, palaces, and temples, deeply covered with the accumulations of many centuries. Enough excavations have been made along the shores of the Tiber at this point to show that the river was bordered with continuous and substantial masonry quays, flanked on the land side by successions of great warehouses, obviously designed to receive grain, wine, oil, and other products of the time. The entrance to this harbor was difficult, as the mouth of the river was shallow, with bars apparently obstructing its approach. There were no jetties, or other seaward works for the protection of vessels desiring to make the harbor. It is stated that during one storm nearly or quite two hundred vessels were destroyed while they were actually in the harbor.

=49. Harbors of Claudius and Trajan.=—The difficulty in entering the mouth of the Tiber prompted the emperor Claudius to construct another harbor to accommodate the vast commerce then centring at the port of Rome. Instead of increasing the capacity of Ostia and opening the mouth of the river by deepening it, he constructed a new harbor on what was then the seashore, a short distance from Ostia, and connected it with the Tiber by a canal, the extension of which by the natural forces of the river has become the Fiumicino, the only present navigable entrance to the river. This harbor was enclosed by two walls stretching out from the shore, and converging on the sea side to a suitable opening left for the entrance of ships. The superficial area of this harbor was about 175 acres, but it became insufficient during the time of Trajan. He then proceeded to excavate inland a hexagonal harbor with a superficial area of about 100 acres, which was connected both with the harbor of Claudius and the canal connecting the latter with the Tiber. These harbor-works were elaborate in their fittings for the accommodation of ships, and were built most substantially of masonry. They showed that at least in some branches of harbor-work the old Romans were as good engineers as in the construction of aqueducts, bridges, and other internal public works. The harbors at ancient Ostia, including those of Claudius and Trajan, were not the only works of their class constructed by the Romans, but they are sufficient to show as great advancement in harbor and dock work as in other lines of engineering.

These harbors were practically defenceless and exposed to the incursions of pirates, which came to be frequently and successfully made in the days of the declining power of Rome. It was therefore rather early in the Christian era that these attacks discouraged, and ultimately drove away, first, the maritime business of the Romans and, subsequently, all the inhabitants of these ports, leaving the pillaged remnants of the vast harbor-works, warehouses, palaces, temples, and other buildings in the ruined condition in which they are now found.

CHAPTER V.

=50. Ancient Engineering Science.=—The state of what may be called the philosophy or science of engineering construction in ancient Rome is admirably illustrated by the work on Architecture by Marcus Vitruvius Pollio, who is ordinarily known as Vitruvius, and who wrote probably a little more than two thousand years ago. He calls himself an architect, and his work is a classic in that profession of which he claims to be a member. Although much of his work was purely architectural, a great portion of it, on the other hand, was not architecture as we now know it, but civil-engineering in the best sense of the term. It must be remembered, therefore, that what is here written applies to that large portion of his work which is purely civil-engineering.

It will be seen that although he understood really little or nothing about the science of civil-engineering as we now comprehend it, he perceived many of the general and fundamental principles of the best practice of that profession and frequently applied them in a manner which would do credit to a modern civil engineer. He not only laid down axioms to govern the design of civil-engineering structures and machinery for the transmission of power, but he also set forth many considerations bearing upon public and private health and the practice of sanitary engineering in a way that was highly creditable to the state of scientific knowledge in his day. Speaking of the general qualifications of an architect, remembering that that word as he understood it includes the civil engineer, he states: “An architect should be ingenious, and apt in the acquisition of knowledge; ... he should be a good writer, a skilful draughtsman, versed in geometry and optics, expert at figures, acquainted with history, informed on the principles of natural and moral philosophy, somewhat of a musician, not ignorant of the sciences both of law and physics, nor of the motions, laws, and relations to each other of the heavenly bodies.” Again he adds: “Moral philosophy will teach the architect to be above meanness in his dealings and to avoid arrogance; it will make him just, compliant, and faithful to his employer; and, what is of the highest importance, it will prevent avarice gaining an ascendency over him; for he should not be occupied with the thoughts of filling his coffers, nor with the desire of grasping everything in the shape of gain, but by the gravity of his manners and a good character should be careful to preserve his dignity.”

These quaint statements of the desirable qualities of a professional man are worthy to be considered rules of good professional living at this time fully as much as they were in the days of old Rome. His esteem for his profession was evidently high, but not higher than the value which every civil engineer should put upon his professional life. The need of a general education for a civil engineer is greater now even than in his day, although musical accomplishments need not be considered as essential in modern engineering practice. That qualification, it is interesting to observe in passing, was inserted by Vitruvius in order to illustrate the wide range of engineering practice in those days when the architect-engineer was called upon, among other things, to construct catapults and other engines of war, in which a nice adjustment of gut ropes was determined by the musical tones emitted under the desired tension.

=51. Ancient Views of the Physical Properties of Materials.=—When it is remembered that the chemical constitution of materials used in engineering was absolutely unknown, that no quantitative determination of physical qualities had been made, and that the first correct conception of engineering science had yet to be acquired, it is a matter of wonder that there had been attained the engineering development evidenced both by ancient writings like those of Vitruvius and great engineering works like those of Rome, in the Babylonian Plain and in Egypt. In discussing the problem of water-supply, he mentions that certain learned ancients, “physiologists and philosophers, maintained that there are four elements—air, fire, water, and earth—and that their mixture, according to the difference of the species, formed a natural mode of different qualities. We must recollect that not only from these elements are all things generated, but that they can neither be nourished nor grow without their assistance.” This view of the construction of material things was not conducive to a clear comprehension of those physical laws which lie at the foundation of engineering science, and it is absolutely essential that these elementary considerations be kept constantly in view in considering the engineering attainments of the Romans and other ancient peoples.

=52. Roman Civil Engineers Searching for Water.=—In ancient times, as at present, it was very important in many cases to know where to look for water, and how to make what might promise to be a successful search for it. Vitruvius states that the sources of water for a supply may easily be found “if the springs are open and flowing above ground.” If the sources are not so evident, but are more obscure, he recommends that “before sunrise one must lie down prostrate in the spot where he seeks to find it, and, with his chin placed on the ground and fixed, look around the place; for, the chin being fixed, the eye cannot range upwards further than it ought and is confined to the level of the place. Then where the vapors are seen curling together and rising into the air, there dig, because those appearances are not discovered in dry places.” This method of discovering water-supply would be considered by modern engineers at least somewhat awkward as well as damp and disagreeable in the early morning hours. It is not more fantastic, however, or less philosophical than the use of the divining-rod, which has been practised in modern times as well as ancient, and is used even in some country districts at the present time.

Vitruvius does not forget that the local features, including both those of soil and of an artificial character, may affect the quality of the water and possibly make it dangerous. He, therefore, sets forth general directions by which good potable water may be found and that of a dangerous nature avoided. The necessity of distinguishing between good and bad water was as present to his mind and to the minds of the old Roman engineers as to civil engineers of the present day, but the means for making a successful discrimination were crude and obviously faulty, and very often unsuccessful. He set forth, what is well known, that rain-water when collected from an uncontaminated atmosphere is most wholesome, but proceeds to give reasons which would not now be

considered in the highest degree scientific.

In Chapter V of his Eighth Book there are described some “means of judging water” so quaint and amusing that they may now well be quoted even though no civil engineer would be bold enough to cite them in modern hydraulic practice. He says: “If it be of an open and running stream, before we lay it on, the shape of the limbs of the inhabitants of the neighborhood should be looked to and considered. If they are strongly formed, of fresh color, with sound legs and without blear eyes, the supply is of good quality.” At another point he comes rather closely to our modern requirements which look to the exclusion of minute and elementary vegetable growths, when he says: “Moreover, if the water itself, when in the spring, is limpid and transparent, and the places over which it runs do not generate moss, nor reeds, nor other filth be near it, everything about it having a clean appearance, it will be manifest by these signs that such water is light and exceedingly wholesome.”

=53. Locating and Designing Conduits.=—In treating of the manner of conducting water in pipes or other conduits, he adverts to the necessity of accurate levelling and the instruments that were used for that purpose. The three instruments which he mentions as being used are called the dioptra, the level (_libra aquaria_), and the chorobates, the latter consisting of a rod about 20 feet in length, having two legs at its extremities of equal length and at right angles to it. Cross-pieces were fastened between the rod and the legs with vertical lines accurately marked on them. These vertical lines were placed in a truly vertical position by means of plumb-lines so that the top of the rod was perfectly level, and the work could thus be made level in reference to it.

In Rome the water was generally conducted either by means of open channels, usually built in masonry for the purpose, or in lead pipes, or in “earthen tubes.” Vitruvius states that the open channels should be as solid as possible, and have a fall of not less than one half a foot in 100 feet. The open channels were covered with an arch top, so that the sun might be kept from striking the water. After bringing the water to the city it was divided into three parts. One was for the supply of pools and fountains, another for the supply of baths, and a third for the supply of private houses. A charge was made for the use of water for the pools, fountains, and baths, and in this way a yearly revenue was obtained. A further charge was also made for the water used in private houses, the revenue from which was applied for the maintenance of the aqueduct which supplied the water. The treatment to be given to the different soils, rocks, and other materials through which the conduit was built which brought the supply to Rome is duly set forth by Vitruvius, and he describes the conditions under which tunnels were constructed. He also described the methods of classifying the lead pipes through which water was conducted from the reservoirs to the various points in the city after stating that they must be made in lengths of not less than 10 feet. The sheets of lead employed in the manufacture of the pipes he describes as ranging in width from 5 inches to 100 inches. The diameter of the pipe would obviously equal very closely the width of the sheet divided by the ratio between the circumference and the diameter of the corresponding circle.

=54. Siphons.=—He speaks of passing valleys in the construction of the conduits by means of what we now call siphons, and prescribes a method for relieving it of the accumulated air. In speaking of earthen tubes or pipes he says that they are to be provided not less than 2 inches thick and “tongued at one end so that they may fit into one another,” the joints being coated with quicklime and oil. He further observes that water conducted through earthen pipes is more wholesome than that through lead, and that water conveyed in lead must be injurious because from it white lead is obtained, which is said to be injurious to the human system. Indeed the effects of lead-poisoning were recognized in those early days, and its avoidance was attempted. In the digging of wells he wisely states that “the utmost ingenuity and discrimination” must be used in the examination of the conditions under which wells were to be dug. He also appreciated the advantage of sedimentation, for he advises that reservoirs be made in compartments so that, as the water flows from one to another, sedimentation may take place and the water be made more wholesome.

=55. Healthful Sites for Cities.=—In the location of cities, as well as of private residences, Vitruvius lays down the general principle that the greatest care should be taken to select sites which are healthy and subject only to clean and sanitary surroundings. Marshy places and those subject to fogs, especially those “charged with the exhalations of the fenny animals,” are to be avoided. Apparently this reference to “fenny animals” may have beneath it the fundamental idea of bacteria, but that is not certain. The main point of all these directions for the securing of sanitary conditions of living is that, so far as his technical knowledge permitted him to go, he insists on the same class of wholesome conditions that would be prescribed by a modern sanitary engineer.

=56. Foundations of Structures.=—Similarly in Chapter V of his First Book, on “Foundations of Walls and Towers,” Vitruvius shows a realization of the principal conditions needful and requisite for the suitable founding of heavy buildings. After a sanitary site for a city is determined and one that can be put in communication with other people “by good roads, and river or sea navigation for the transportation of merchandise,” he proceeds to state that “foundations should be carried down to solid bottom, if such can be found,

and that they should be built thereon of such thickness as may be necessary for the proper support of that part of the wall standing above the natural level of the ground. They should be of the soundest workmanship, and materials of greater thickness than the walls above." Again, in speaking of the foundations supporting columns, he states: "The intervals between the foundations brought up under the columns should be either rammed down hard, or arched, so as to prevent the foundation-piers from swerving. If solid ground cannot be come to, and the ground be loose or marshy, the place must be excavated, cleared, and either alder, olive, or oak piles, previously charred, must be driven with a machine as close to each other as possible and the intervals between the piles filled with ashes. The heaviest foundations may be laid on such a base." It is thus seen that pile foundations were used by the Romans, and that the piles were driven with a machine. It would be difficult to give sounder general rules of practice even after more than two thousand years' additional experience.

=57. Pozzuolana and Sand.=—Of all the materials which were useful to the Romans in their various classes of construction, including the foundations of roads, "pozzuolana" must have been the most useful, and that which contributed more to the development of successful construction in Rome than any other single agent. Vitruvius speaks of it frequently and gives rules not only for the use of it in the production of mortar and concrete, but also lays down at considerable length the treatment which should be given to lime in order to produce the best results. It was common, according to his statements, to use two measures of "pozzuolana" with one of lime in order to obtain a suitable cementing material. This mixture was used in varying proportions with sand and gravel or broken stone to produce concrete. He describes the various grades of sands to be found about Rome and the manner of using them. The statement is made that sand should be free of earth and that the best of it was such as to yield a "grating sound" when "rubbed between the fingers." This is certainly a good engineering test of sand. He prefers pit-sand to either river- or sea-sand; indeed throughout all his directions regarding this particular class of construction his rules might be used at the present time with perfect propriety.

=58. Lime Mortar.=—The old Romans had also discovered the advisability of allowing lime to stand for a considerable period of time after slaking. This insured the slaking of all those small portions which were possibly a little hydraulic and therefore slaked very slowly. He prescribes as a good proportion two parts of sand to one of lime, and also mentions the proportion of three to one. He attempts to explain the setting, as we term it, of lime, but his explanation in obscure terms, involving qualities of the elements of fire and air, is not very satisfactory.

=59. Roman Bricks according to Vitruvius.=—As is well known, the Romans were good brick-makers, and they were well aware that bricks made from "ductile and cohesive" "red or white chalky" earth were far preferable to those made of more gravelly or sandy clay. The Roman bricks were both sun-dried and kiln-burned.

=60. Roman Timber.=—Timber was a material much used by the Romans, and the greater part of that which they used probably was grown in Italy, although considerable quantities were imported from other localities. Vitruvius writes in considerable detail concerning the selection of timber while standing, as well as in reference to its treatment before being used in structures. Like every material used by the old Romans in construction, the various kinds and qualities of timber received careful study from them, and they were by no means novices in the art of producing the best results from those kinds of timber with which they were familiar.

=61. The Rules of Vitruvius for Harbors.=—In Chapter XII of his Fifth Book Vitruvius lays down certain general rules for the selection and formation of harbors, and it is known that the Romans were familiar with elaborate and effective harbor construction, as is shown by that at Ostia. He appreciates that a natural harbor is one which has "rocks or long promontories jutting out, which from the shape of the place form curves or angles," and that in such places "nothing more is necessary than to construct portices and arsenals around them, or passages to the markets." He then proceeds to state that if such a natural formation is not to be found, and that if "on one side there is a more proper shore than on the other, by means of building or of heaps of stones, a projection is run out, and in this the enclosures of harbors are formed." He then proceeds to explain how "pozzuolana" and lime, in the proportion of two of the former to one of the latter, are used in subaqueous construction. He also prescribed a mode of building a masonry wall up from the bottom of an excavation made within what we should call a coffer-dam, formed, among other things, "of oaken piles tied together with chain pieces." The Romans knew well how to select harbors and how to construct in an effective manner the artificial works connected with them, although it appears that the effects of tidal and river currents in estuaries were neither well understood in themselves nor in their transporting power of the solid material which those currents eroded.

=62. The Thrusts of Arches and Earth; Retaining-walls and Pavements.=—Although the Romans possessed little or no knowledge of analytical mechanics they attained to some good qualitative mechanical conceptions. Among other things they understood fairly well the general character of the thrust of an arch and the tendency of the earth to overthrow a retaining-wall. They knew that a

massive abutment was needed to receive safely the thrust of an arch, and they counterforted or buttressed retaining-walls in order to hold them firmly in place. They also realized the danger of wet earth pressing against a retaining-wall, and even made a series of offsets or teeth on the inside of the wall on which the earth rested in order to aid in holding the wall in place. Vitruvius recommends as a safeguard against the pressure of earth wet by winter rains that “the thickness of the wall must be proportioned to the weight of earth against it,” and that counterforts or buttresses be employed “at a distance from each other equal to the height of the foundations, and of the same width as the foundations,” the projections at the bottom being equal in thickness to that of the wall, and diminishing toward the top.

He gives in considerable detail instructions for the forming of pavements and stucco work, so many examples of which are still existing in Rome. These rules are in many respects precisely the same as would govern the construction of similar work at the present time. There are also described in a general way the methods of producing white and red lead, as pigments of paints, and a considerable number of other pigments of different colors.

=63. The Professional Spirit of Vitruvius.=—It is evident, from many passages in the writings of this Roman architect-engineer, that the ways of the professional men in old Rome were not always such as led to his peace of mind. Vitruvius utters bitter complaints which show that he did not consider purely professional knowledge and service to be adequately recognized or appreciated by his countrymen. He writes that in the city of Ephesus an ancient law provided that if the cost of a given work completed under the plans and specifications of an architect did not exceed the estimate, he was commended “with decrees and honors,” but if the cost exceeded the estimate with 25 per cent added thereto, he “was required to pay that excess out of his own pocket.” Then he exclaims, “Would to God that such a law existed among the Roman people, not only in respect to their public but also to their private buildings, for then the unskilful could not commit their depredations with impunity, and those who were the most skilful in the intricacies of the art would follow the profession!”

=64. Mechanical Appliances of the Ancients.=—It is well known that the ancients possessed at least some simple types of machines, for the reason that they raised many great stones to a considerable height in completed works after having transported them great distances from the quarries whence they were taken. Undoubtedly these machines were of a simple and crude character and were made effective largely by the power of great numbers of men. We are not acquainted with all the details of these machines, although the general types are fairly well known. The elementary machines, including the lever, the inclined plane, the pulley, and the screw, which is only an application of the inclined plane, were all used not only by the Romans, but probably by every civilized ancient nation. Vitruvius describes a considerable number of these machines, and from his descriptions it is clear that they had wide application in the structural works of the Romans. The block and fall, as we term the pulley at the present time, was a common machine in the plant of a Roman constructor, as were also various modifications and applications of the lever, the roller, and the inclined plane.

=65. Unlimited Forces and Time.=—It is neither surprising nor very remarkable that with the use of these simple machines, aided by a practically unlimited number of men, the necessary raising or other movement of heavy weights was accomplished by the Romans and other ancient peoples. It is to be borne in mind that the element of time was of far less consequence in those days than at present, and that the rate of progress made in the construction of most if not all ancient engineering works was what we should consider intolerably slow.

PART II.

BRIDGES.

CHAPTER VI.

=66. Introductory.=—Although the bridge structures of to-day serve the same general purposes as those served by the most ancient structures, they are very different engineering products. It is not long, in comparison with the historic and prehistoric periods during which bridges have been built, since the science of mechanics has been sufficiently developed to make bridge design a rational procedure; and it is scarcely more than a century since the principles of mechanics were first applied to the design of bridge structures in such a way as to determine even approximately the amount of stress produced in any member by the imposed load. Naturally the first efforts made toward a truly rational bridge design were in fact simple and crude and only loosely approximate in their results. Probably the first analytic treatment of bridges was given to the design of arches in masonry and then in cast-iron. As the action of forces in structures became better known through the development of mechanical science, the applications of the

latter became less crude and approximate and the approach to the refined accuracy of the present day was begun.

=67. First Cast-iron Arch.=—These older structures, nearly all of them arches or more or less related to the arch, first appeared in cast-iron in the latter part of the eighteenth century, when nothing like an accurate analysis of forces developed by the application of a given load was known. The first cast-iron arch was erected over the Severn in England near Coalbrookdale in the year 1779. This bridge had a span of 100 feet, and the under surface of the arch or soffit at the crown was 45 feet above the points at the abutment from which the arch sprang, or, as civil engineers put it, the arch had a span of 100 feet and a rise or versine of 45 feet. Other cast-iron arches were built in England soon after.

=68. Early Timber Bridges in America.=—Timber bridges have been built since the earliest historic periods and even earlier, but the widest and boldest applications of timber to bridge structures have been made in this country, beginning near the end of the eighteenth century and running to the middle of the nineteenth century, when timber began to be displaced by iron. Timber bridges and those of combined iron and timber are built to some extent even at the present day, but the most extended work of this class is to be found in the period just named.

In 1660 what was called the “Great Bridge” was built across the Charles River near Boston, and was a structure on piles. Other similar structures followed, but the first long-span timber bridge, where genuine bridge trussing or framing was used, appears to have been completed in 1792, when Colonel William P. Riddle constructed the Amoskeag Bridge across the Merrimac River at Manchester, N. H., in six spans of a little over 92 feet from centre to centre of piers. From that time timber bridges, mostly on the combined arch and truss principle, were built, many of them examples of remarkably excellent engineering structures for their day. Among these the most prominent were the Bellows Falls Bridge, in two spans of 184 feet each from centre to centre of piers, over the Connecticut River, built in 1785-92 by Colonel Enoch Hale; the Essex-Merrimac Bridge over the Merrimac River, three miles above Newburyport, Mass., built by Timothy Palmer in 1792, consisting actually of two bridges with Deer Island between them, the principal feature of each being a kind of arched truss of 160 feet span on one side of the island and 113 feet span on the other; the Piscataqua Bridge, seven miles above Portsmouth, N. H., in which a “stupendous arch of 244 feet cord is allowed to be a masterly piece of architecture, planned and built by the ingenious Timothy Palmer of Newburyport, Mass.,” in 1794; the so-called “Permanent Bridge” over the Schuylkill River at Philadelphia, built in 1804-06 in two arches of 150 feet and one of 195 feet, all in the clear, after the design of Timothy Palmer; the Waterford Bridge over the Hudson River, built in 1804 by Theodore Burr, in four combined arch and truss spans, one of 154 feet, one of 161 feet, one of 176 feet, and the fourth of 180 feet, all in the clear; the Trenton Bridge, built in 1804-06 over the Delaware River at Trenton, N. J., by Theodore Burr, in five arch spans of the bowstring type, ranging from 161 feet to 203 feet in the clear; a remarkable kind of wooden suspension bridge built by Theodore Burr in 1808 across the Mohawk River at Schenectady, N. Y., in spans ranging in length from 157 feet to 190 feet; the Susquehanna Bridge at Harrisburg, Pa., built by Theodore Burr in 1812-16 in twelve spans of about 210 feet each; the so-called Colossus Bridge, built in 1812 by Lewis Wernwag over the Schuylkill River at Fairmount, Pa., with a clear span of 340 feet 3¾ inches; the New Hope Bridge, built in 1814 over the Delaware River, in six 175 feet combined arch and truss spans, and a considerable number of others built by the same engineer.

Some of these wooden bridges, like those at Easton, Pa., and at Waterford, N. Y., remained in use for over ninety years with only ordinary repairs and with nearly all of the timber in good condition. In such cases the arches and trusses have been housed and covered with boards, so as to make what has been commonly called a covered bridge. The curious timber suspension bridge built by Theodore Burr at Schenectady was used twenty years as originally built, but its excessive deflection under loads made it necessary to build up a pier under the middle of each span so as to support the bridge structure at those points. These bridges were all constructed to carry highway traffic, but timber bridges to carry railroad traffic were subsequently built on similar plans, except that Burr’s plan of wooden suspension bridge at Schenectady was never repeated.

FIG. 2.]

=69. Town Lattice Bridge.=—A later type of timber bridge which was most extensively used in this country was invented by Ithiel Town in January, 1820, which was known as the Town lattice bridge. This timber bridge was among those used for railroad structures. As shown by the plan it was composed of a close timber lattice, heavy plank being used as the lattice members, and they were all joined by wooden pins at their intersections. This type of timber structure was comparatively common not longer ago than twenty-five years, and probably some structures of its kind are still in use. The close latticework with its many pinned intersections made a very safe and strong frame-work, and it enjoyed deserved popularity. It was the forerunner in timber of the modern all-riveted iron and steel lattice truss. It is of sufficient significance to state, in connection with the Town lattice, that its inventor claimed that his trusses could be made of wrought or cast-iron as well as timber. In many cases timber arches were combined with them.

[Illustration: FIG. 3.]

=70. Howe Truss.=—The next distinct advance made in the development of bridge construction in the United States was made by brevet Lieutenant-Colonel Long of the Corps of Engineers, U.S.A., in 1830-39, and by William Howe, who patented the bridge known as the Howe truss, although the structure more lately known under that name is a modification of Howe's original truss. Long's truss was entirely of timber, including the keys, pins, or treenails required, and it was frequently built in combination with the wooden arch. The truss was considerably used, but it was not sufficiently popular to remain in use.

[Illustration: Howe Truss-Bridge.]

[Illustration: FIG. 4.]

The Howe truss was not an all-wooden bridge. The top and bottom horizontal members, known as "chords," the inclined braces between them and the vertical end braces, all connecting the two chords, were of timber, and they were bolted at all intersections; but the vertical braces were of round iron with screw ends. These rods extended through both chords and received nuts at both ends pressing on cast-iron washers through which the rods extended. These wrought-iron round rods were in groups at each panel-point, numbering as many as existing stresses required. The ends of the timber braces abutted against cast-iron joint-boxes. The railroad floor was carried on heavy timber ties running entirely across the bridge and resting upon the lower chord members. It was a structure simple in character, easily framed, and of materials readily secured. It was also easily erected and could quickly be constructed for any reasonable length of span. It possessed so many merits that it became widely adopted and is used in modified form at the present day, particularly on lines where the first cost of construction must be kept as low as possible. The large amount of timber in it and the simple character of its wrought-iron or steel members greatly reduces its first cost.

=71. Pratt Truss.=—In 1844 the two Pratts, Thomas W. and Caleb, patented the truss, largely of timber, which has since been perpetuated in form by probably the largest number of iron and steel spans ever constructed on a single type. The original Pratt trusses had timber upper and lower chords, but the vertical braces were also made of timber instead of iron, while the inclined braces were of round wrought-iron with screw ends, the reverse of the web arrangement in the Howe type. This truss had the great advantage of making the longest braces (of iron) resist tension only, while the shorter vertical braces resist compression. As a partially timber bridge it could not compete with the Howe truss, because it contained materially more iron and consequently was more costly. This structure practically closed the period of development of timber bridges.

=72. Squire Whipple's Work.=—What amounted to a new epoch in the development of bridge construction in this country practically began in 1840 when Squire Whipple built his first bowstring truss with wrought-iron tension and cast-iron compression members. While the Pratts and Howe had begun to employ to some extent the analysis of stresses in the design of their bridge members, the era of exact bridge analysis began with Squire Whipple. He subjected his bridge designs to the exacting requirements of a rational analysis, and to him belongs the honor of placing the design of bridges upon the firm foundation of a systematic mathematical analysis.

=73. Character of Work of Early Builders.=—The names of Palmer, Burr, and Wernwag were connected with an era of admirable engineering works, but, with bridge analysis practically unknown, and with the simplest and crudest materials at their disposal, their resources were largely constituted of an intuitive engineering judgment of high quality and remarkable force in the execution of their designs never excelled in American engineering. They occasionally made failures, it is true, but it is not recorded that they ever

made the same error twice, and the works which they constructed form a series of precedents which have made themselves felt in the entire development of American bridge-building.

CHAPTER VII.

=74. Modern Bridge Theory.=—The evolution of bridge design having reached that point where necessity of accurate analysis began to make itself felt, it is necessary to recognize some of the fundamental theoretical considerations which lie at the base of modern bridge theory, and which involve to a considerable extent that branch of engineering science known as the elasticity or strength of the materials used in engineering construction.

The entire group of modern bridge structures may be divided into simple beams or girders, trusses, arches, suspension bridges, and arched ribs, each class being adapted to carry either highway or railway traffic. That class of structure known as beams or girders is characterized by very few features. There are solid beams like those of timber, with square or rectangular cross-sections, and the so-called flanged girders which are constituted of two horizontal pieces, one at the top and the other at the bottom, connected by a vertical plate running the entire length of the beam. The fundamental theory is identically the same for both and is known as the “common theory of flexure,” i.e., the theory of beams carrying loads.

If an ordinary scantling or piece of timber of square or rectangular cross-section, like a plank or a timber joist, so commonly used for floors, be supported at each end, it is a matter of common observation that it will sustain an amount of load depending upon the dimensions of the stick and length of span. When such a bar or piece is loaded certain forces or stresses, as they are called, are brought into action in its interior. The word “stress” is used simply to indicate a force that exists in the interior of any piece of material. It is a force and nothing else. It is treated and analyzed in every way precisely as a force. If the stresses or forces set up by the loading in the interior of the bar become greater than the material can resist, it begins to break, and the breaking of that portion of the timber in which the stresses or forces are greatest constitutes its failure. The load which produces this failure in a beam is called the breaking load of the beam. In engineering practice all beams are so designed or proportioned that the greatest load placed on them shall be only a safe percentage of the breaking load; the safe load usually being found between ■ and ■ of the breaking load. In most buildings the safe or working load, as it is called, is probably about ¼ of the breaking load.

[Illustration: FIG. 5.]

[Illustration: FIG. 6.]

[Illustration: FIG. 7.]

=75. The Stresses in Beams.=—The proper design of beams or girders to carry prescribed loads is based upon the stresses which are developed or brought into action by them. It can easily be observed that if a beam supported at each end be composed of a number of thin planks or boards placed one upon the other, it will carry very little load. Each plank or board acts independently of the others and a very small load will cause a sag, as shown in Fig. 6. If there be taken, on the other hand, a beam made of a single stick of timber of the same width and depth as the number of planks shown in Fig. 6, so as to secure the solid beam shown in Fig. 7, it is a further common observation that this latter beam may carry many times the load which the laminated beam, shown in Fig. 6, sustains. The thin planks or boards readily slide over each other, so that the ends present the serrated form shown in Fig. 6. The preventing of this sliding is the sole cause of the greatly increased stiffness of the solid beam shown in Fig. 7, for there is thus developed along the imaginary horizontal sections in the solid beam of Fig. 7 what are called shearing forces or stresses; and since they exist on horizontal sections or planes running throughout the entire length of the beam, they are called horizontal shears.

At each end of the beam shown in Fig. 7 there will be an upward or supporting force exerted by the abutments on which the ends of the beam rest. Those upward or supporting forces are shown at _R_ and _R′_ and are called reactions, because the abutments, so to speak, react against the ends of the beam when the latter is loaded. These reactions depend for their value on the amount and the location of the loading which the beam carries. Obviously these upward forces or reactions tend to cut or shear off the ends of the beam immediately above them, and if the loads were sufficiently large and the beam kept from bending, the reactions would actually shear off those ends, just as punches or shears in a machine-shop actually shear off the metal when the rivet-hole is punched, or when a plate is cut by shearing into two parts. The beam, however, bends or sags before shearing apart actually takes place.

[Illustration: FIG. 8.]

[Illustration: FIG. 9.]

=76. Vertical and Horizontal Shearing Stresses.=—If it be supposed that the length of the beam is divided into a great number of parts by imaginary vertical lines, like those shown in Fig. 8, then vertical shearing forces will be developed in those vertical planes and sometimes, though not often, they are enough to cause failure. It is not an uncommon thing, on the other hand, in timber to have actual shearing failure take place along a horizontal plane through the centre of the beam. Indeed this is recognized frequently as the principal method of failure in very short spans. When this horizontal shearing failure takes place, the upper and lower parts of the beam slide over each other and act precisely like the group of planks shown in Fig. 6.

If, then, the loaded beam be divided by vertical and horizontal planes into the small rectangular portions shown in Figs. 8 and 9, on each such vertical and horizontal imaginary plane there will be respectively vertical and horizontal shearing forces, which are shown by arrows in Fig. 9. It will be noticed in that figure that in each corner of the rectangle the two shearing forces act either toward or from each other; in no case do the two adjacent shearing forces act around the rectangle in the same direction. This is a condition of shearing stresses peculiar to the bent beam. It can be demonstrated by theory and is confirmed by experiment. There is a further peculiarity about these shearing forces which act in pairs either toward or from the same angle in any rectangle, and it is that the two stresses adjacent to each other have precisely the same value per square inch (or any square unit that may be used) of the surface on which they act. These stresses per square inch vary, however, either along the length of the beam or as the centre line of any normal cross-section is departed from. They are greatest along the centre line or central horizontal plane represented by _AB_, and they are zero at the top and bottom surfaces of the beam.

Inasmuch as the horizontal shear along the plane _A■B■_ is less than that along _AB_ in Fig. 9, a part of the latter has been taken up by the horizontal fibres of the beam lying between the two planes. In other words, the horizontal layer of fibres at _A■B■_ is subjected to a greater stress or force along its length than at _AB_. The same general observation can be made in reference to any horizontal layer of fibres that is farther away from the centre than another. Hence the farther any fibre is from the centre the greater will be the stress or force to which it is subjected in the direction of its length. It results, then, that the horizontal layers of fibres which are farthest from the centre line of the beam, i.e., those at the exterior surfaces, will be subjected to the greatest force or stress, and that is precisely what exists in a loaded beam whatever the material may be.

=77. Law of Variation of Stresses of Tension and Compression.=—Since a horizontal beam supported at each end is deflected or bent downward when loaded, it will take a curved form like that shown in either Fig. 7 or Fig. 10; but this deflection can only take place by the shortening of the top of the beam and the lengthening of its bottom. This shows that the upper part of the beam is compressed throughout its entire length, while the lower part is stretched. In engineering language, it is stated that the upper part of the beam is thus subjected to compression and the lower part to tension. The horizontal layers or fibres receive their tension and compression from the vertical and horizontal shearing forces in the manner already explained. If the conditions of loading of the bent beam should be subjected to mathematical analysis, it would be found that throughout the originally horizontal plane _AB_, Fig. 7, passing through the centre of each section there would be no stress of either tension or compression, although the horizontal shearing stress there would be a maximum. Further, as this central plane is departed from the stress of tension or compression per square inch in any vertical section would be found to increase directly as the distance from it. This is a very simple law, but one of the greatest importance in the design of all beams and girders, whatever may be the form or size of cross-section. It is a law, which applies equally to the solid timber beam and to the flanged steel girder, whether that girder be rolled in the mill or built up of plates and angles or other sections in the shop. It is a fundamental law of what is called the common theory of flexure, and is the very foundation of all beam and girder design. The horizontal plane represented by the line _AB_ in Fig. 8, along which there is neither tension nor compression, is called the “neutral plane,” and its intersection with any normal cross-section of the beam is called the “neutral axis” of that section. Mathematical analysis shows that the neutral plane passes through the centres of gravity of all the normal sections of the beam and, hence, that the neutral axis passes through the passes through the centre of gravity of the section to which it belongs.

=78. Fundamental Formulæ of Theory of Beams.=—The fundamental formulæ of the theory of loaded beams may be quite simply written. Fig. 10 exhibits in a much exaggerated manner a bent beam supporting any system of loads _W■_, _W■_, _W■_, etc., while Fig. 11 shows a normal cross-section of the same beam. In Fig. 10 _AB_ is the neutral line, and in Fig. 11 _CD_ is the neutral axis passing through the centre of gravity, _c.g._, of the section.

[Illustration: FIG. 10.]

[Illustration: FIG. 11.]

If _a_ is the amount of force or stress on a square inch (or other square unit), i.e., the intensity of stress, at the distance of unity from the neutral axis _CD_ of the section, then, by the fundamental law already stated, the amount acting on another square inch at any other distance _z_ from the neutral axis will be _az_. This quantity is called the “intensity of stress” (tension or compression) at the distance _z_ from the neutral axis. Evidently it has its greatest values in the extreme fibres of the section, i.e., _ad_ and _ad_■. At the neutral axis _az_ becomes equal to zero. _FG_ in Fig. 11 represents the same line as _FG_ in Fig. 10. If the line _FH_ in Fig. 11 be laid down equal to _ad_ and at right angles to _FG_, and if _O_ represent the centre of gravity, _c.g._, of the section, then let the straight line _LH_ be drawn. Any line drawn parallel to _FH_ from _FG_ to _LH_ will represent the intensity of stress in the corresponding part of the beam’s cross-section. Obviously, as these lines are drawn in opposite directions from _FG_, those above _O_ will indicate stress of one kind, and those below that point stress of another kind, i.e., if that above be tension, that below will be compression. It can be demonstrated by a simple process that the total tension on one side of the neutral axis is just equal to the total compression on the other side, and from that condition it follows that the neutral axis must pass through the centre of gravity or centroid of the section.

Returning to the left-hand portion of Fig. 11, let _dA_ represent a very small portion of the cross-section; then will _az. dA_ be the amount of stress acting on it. The moment of this stress or force about the neutral axis will be

azdA·z = az²·dA.

If this expression be applied to every small portion of the entire section, the aggregate or total sum of the small moments so found will be the moment of all the stresses in the section about the neutral axis. That moment will have the value

_M_ = ∫_az²·dA_ = _a_ ∫_z²·dA_ = _aI_. (1)

In equation (1) the symbol ∫ means that the sum of all the small quantities to the right of it is taken, and _I_ stands for that sum which, in the science of mechanics, is called the moment of inertia of the cross-section about its neutral axis. The value of the quantity _I_ may easily be computed for all forms of section. Numerical values belonging to all the usual forms employed in engineering practice are found in extended tables in the handbooks of the large iron and steel companies of the country, so that its use ordinarily involves no computations of its value.

Equation (1) may readily be changed into two other forms for convenient practical use. In Fig. 10 _mn_ is supposed to be a very short portion of the centre line of the beam represented by _dl_. Before the beam is bent the section _FG_ is supposed to have the position _MN_ parallel to _PQ_. Also let _u_ be the small amount of stretching or compression (shortening) of a unit’s length of fibre at unit’s distance from the centre line _AB_ of the beam, then will _udl_ and _uzdl_ be the short lines parallel to _GN_ in the triangle _GmN_ shown in the figure. The point _C_ is the centre of curvature of the line _mn_, and _Cn = Cm_ is the radius. The two triangles _Cnm_ and _mNG_ are therefore similar, hence

udl _mn_ _dl_ I ------- = ---- = ----- ∴ u = ---. (2) I ρ ρ ρ

If the quantity called the coefficient or modulus of elasticity be represented by _E_, then, by the fundamental law of the theory of elasticity in solid bodies,

_a = Eu_. (3)

As has already been shown, the greatest stresses (intensities) in the section are +_ad_ (tension) and -_ad_■ (compression). If _K_ represent that greatest intensity of stress, then

_K_ _K = ad_, and _a_ = ----. (4) _d_

If the value of _a_ from equation (4) be substituted in equation (1),

_KI_ _M_ = -----. (5) _d_

=79. Practical Applications.=—Equation (5) is a formula constantly used in engineering practice. All quantities in the second member are known in any given case. _K_ is prescribed in the specifications, and is known as the “working resistance” in the design of beams and girders. For rolled steel beams in buildings it is frequently taken at 16,000 pounds, i.e., 16,000 pounds per square inch, about one fourth the breaking strength of the steel. In railroad-bridge work it may be found between 10,000 and 12,000

pounds, or approximately one fifth of the breaking strength of the steel. The quantities _I_ and _d_ depend upon the form and dimensions of the cross-section, and are either known or may be determined. The quotient _I ÷ d_ is now known as the “section modulus,” and its numerical values for all forms of rolled beams can be found in published tables. The use of equation (5) is therefore in the highest degree convenient and practicable.

=80. Deflection.=—It is frequently necessary, both in the design of beams and framed bridges, to ascertain how much the given loading will cause the beam or truss to sag, or, in engineering language, to deflect below the position occupied when unloaded. The deflection is determined by the sagging in the vertical plane of the neutral line below its position when the structure carries no load. In Fig. 10 the curved line _AB_ is the neutral line of the beam when supporting loads. If the loads should be removed, the line _AB_ would return to a horizontal position. The line drawn horizontally through _A_ and indicated by _x_ is the position of the centre line of the beam before being bent. The vertical distance _w_ below this horizontal line shows the amount by which the point at the end of the line _x_ is dropped in consequence of the flexure of the beam. The vertical distance _w_ is therefore called the deflection. Evidently the deflection varies with the amount of loading and with the distance from the end of the beam. The curved line _AB_ in one special case only is a circle. The general character of that curve is determined by the loading and the length of span.

In order that the deflection may be properly considered it is necessary that the relation between _x_ and _w_ shall be established for all conditions of loading and length of span. If the value of _u_ from equation (2) be placed in equation (3), there will result

$$E\,a = \frac{}{\rho}. \quad (6)$$

If the value of _a_ from equation (6) be substituted in the last member of equation (1), there will at once result

$$EI\,M = \frac{}{\rho}. \quad (7)$$

It is established by a very simple process in differential calculus that

$$I\,\frac{d^2w}{} = \frac{}{dx^2}. \quad (8)$$

Hence, substituting from equation (8) in equation (7),

$$\frac{d^2w}{}\,M = EI\,\frac{}{dx^2}. \quad (9)$$

Equation (9) may be used by means of some very simple operations in integral calculus to determine the value of _w_ in terms of _x_ and the loads on the beam when the value of the bending moment _M_ is known, and the procedures for determining that quantity will presently be given.

Using the processes of the calculus, the two following equations will immediately be found:

$$\frac{dw}{dx} = \frac{1}{EI}\int M\,dx; \quad (10)$$

$$w = \frac{1}{EI}\iint M\,dx^2 \quad (11)$$

As already explained, numerical values for both _E_ and _I_ may be taken at once from tables already prepared for all materials and for all shapes of beams ordinarily employed in structural work, so that equation (11) enables the deflection or sag of the bent beam to be computed in any case. The expression _dw/dx_ is the tangent of the angle made by the neutral line of a bent beam with a horizontal line at any given point, and it is a quantity that it is sometimes necessary to determine. _dw_ and _dx_ are indefinitely short vertical and horizontal lines respectively, as shown immediately to the left of _B_ in Fig. 10.

Equation (11) is not used in structural work nearly as much as equation (5), but both of them are of practical value and involve only simple operations in their use.

=81. Bending Moments and Shears with Single Load.=—The second members of equations (5) and (9) exhibit values of the moments of the internal forces or stresses in any normal cross-section of a bent beam about the neutral axis of the section, while the values of _M_ must be expressed in terms of the external forces or loading. Inasmuch as the latter moment develops just the internal moment, it is obvious that the two must be equal. In order to write the value of the external moment in terms of any loading, it is probably the simplest procedure to consider a beam carrying a single load. In Fig. 12, _AB_ is such a beam, and _W_ is a load which may be placed anywhere in the span, whose length is _l_. The distances of the load from the abutments are represented by _x_■ and _x_■. The reactions or supporting forces exerted under the ends of the beam at the abutments are shown by _R_ and

_R′_. The reactions, determined by the simple law of the lever, are

_x■ x■_ _R = W_ ---- and _R■ = W_ ---- (12) _l l_

The greatest bending moment in the beam will occur at the point of application of the load, and its value will be

_x■x■_ _M■ = Rx■ = W_ ------- = -_R■x■_. (13) _l_

[Illustration:

_Wx■x■_ _M■ = Rx■ = -R■x■_ = ------- _l_

FIG. 12.]

The bending moments at the end of the beam are obviously zero, and the second and fourth members of equation (13) show that the moment increases directly as the distance from either end. Hence in the lower portion of Fig. 12, at _D_, immediately under the load _W_, the line _DC_ is laid off at any convenient scale to represent the moment _M_■. The straight lines _AC_ and _CB_ are then drawn. Any vertical intercept, as _FH_ or _KL_, between _AB_ and either _AC_ or _CB_ will represent the bending moment at the corresponding point in the beam. The simple triangular diagram _ACB_ therefore represents the complete condition of bending of the beam under the single load _W_ placed at any point in the span.

The beam _AB_ is supposed for the moment to have no weight. Consequently the only force acting upon the portion of the beam _AO_ is the reaction _R_, and, similarly, _R■_ is the only force acting upon the portion _OB_. Obviously so far as the simple action of these two forces or reactions is concerned, the tendency of each is to cause vertical slices of the beam, so to speak, to slide over each other. In other words, in engineering language, the portion _AO_ of the beam is subjected to the shear _S = R_, while _OB_ is subjected to the shear _S■ = -R■_. The cross-sectional area of the beam must be sufficient to resist the shear _S_ or _S■_. The upper part of Fig. 13 shaded with broken vertical lines indicates this condition of shear. It is evident from this simple case that the total vertical shears at the ends of any beam will be the reactions or supporting forces exerted at those ends, and that each will remain constant for the adjoining portion of the beam.

The third member of equation (13) shows that the greatest bending moment _M_■ in the beam varies as the product _x_■_x_■ of the segments of the span. That product will have its greatest value when _x_■ = _x_■. Hence _a simple beam loaded by a single weight will be subjected to the greatest possible bending moment when the weight is placed at the middle of the span, at which point also that moment will be found_.

=82. Bending Moments and Shears with any System of Loads.=—The general case of a simple beam loaded with any system of weights whatever may be represented in Fig. 13, in which the beam of Fig. 12 is supposed to carry three loads, _w_■, _w_■, _w_■. The spacing of the loads is as shown. The reactions or supporting forces _R■_ are determined precisely as in Fig. 12, each reaction in this case being the resultant of three loads instead of one. Applying the law of the lever as before, the reaction _R_ will have the value

_d d + c d + c + b_ _R = W■--- + W■------- + W■----------_. (14) _l l l_

A similar value may be written for _R■_, but it is probably simpler, after having found one reaction, to write

_R′ = W■ + W■ + W■ - R_. (15)

As the beam is supposed to have no weight, no load will act upon the beam between the given weights. The bending moments at the points of application of the three weights or loads will be

_M■_ = _Ra_, } _M■_ = _R_(_a + b_) - _W■b_, } (16) _M■_ = _R_(_a + b + c_) - _W■_(_b + c_) - W■c_.}

After substituting the value of _R_ from equation (14) in equations (16) the values of the latter are at once known.

[Illustration: FIG. 13.]

The bending produced by each weight will also be represented precisely like that in Fig. 12. The triangle _ANB_ represents the bending produced by _W_■; _AOB_ the bending produced by _W_■; and _APB_ the bending produced by _W_■. The resultant bending effect produced by the three loads or weights acting simultaneously is simply the summation of the three effects each due to a single load. Hence _DC_ is erected vertically through the point of application of _W_■, so as to equal _DN_ added to the two

vertical intercepts between _AB_ and _AP_, and _AB_ and _AO_. Similarly, _HF_ is equal to _HO_ added to the intercepts between _AB_ and _AP_, and _AB_ and _BN_. Finally, _KL_ is equal to _PL_ added to the other two intercepts, one between _AB_ and _BN_, and the other between _AB_ and _BO_. Straight lines then are drawn through _A_, _C_, _F_, _K_, and _B_. Any vertical intercept between _AB_ and _ACFKB_ will represent the bending moment in the beam at the corresponding point. Obviously any number of loads of any magnitude, or a uniform load, may be treated in precisely the same way.

An important practical rule can readily be deduced from the equations (16), each one of which may be regarded as a general equation of moments. If the system of three, or any other number of loads, be moved a small distance Δ_x_, while they all remain separated by the same distances as before, the bending moment _M_ will be changed by the amount shown in equation (16_a_):

ΔM = RΔx - W■Δx - W■Δx - etc. (16_a_)

If the notation of the differential calculus be used by writing the letter _d_ instead of Δ, and if both members of equation (16_a_) be then divided by _dx_, equation (16_b_) will result:

_ΔM dM_ --- = ---- = _R - W■ - W■_ - etc. = shear. (16_b_) _Δx dx_

The second member of this equation shows the sum of all the external forces acting on one portion of the beam, that portion being limited by the section about which the moment _M_ acts. That sum of all the external forces, as given by the second member of equation (16_b_), is evidently the total transverse shear at the section considered. Equation (16_b_) then shows, in the language of the differential calculus, that the first derivative of _M_ in respect to _x_ is equal to the total transverse shear. It is further established in the differential calculus that whenever a function, such as _M_, the bending moment, is a maximum or a minimum, the first derivative is equal to zero. The application of this principle to equation (16_b_) shows that the bending moment in any beam or truss has its greatest value wherever the shear is zero. Hence, in order to determine at what section the bending moment has its greatest value in any loaded beam carrying a given system of loads, it is only necessary to sum up all the forces or loads, including the reaction _R_, on that beam from one end to the point where that sum or shear is zero; at this latter point the greatest moment sought will be found. This is a very simple method of determining the section at which the greatest moment in the beam exists.

The preceding formulæ and diagrams may be extended to include any number of loads, and they are constantly used in engineering practice, not only for beams and girders in buildings, but also for bridges carrying railroad trains. Whatever may be the number of loads, the expressions for the bending moments at the various points of application of those loads are to be written precisely as indicated in equations (16). When the number of loads becomes great the number of terms in the equations correspondingly increase, but in reality they are just as simple as those for a smaller number of loads.

The diagram for the vertical shear in this beam is the lower part of Fig. 13. As in the case of Fig. 12 the shear at _A_ is the reaction _R_, as it is _R■_ at the other end of the beam. The shear in the portion _AD_ of the beam has the value _R_, but in passing the point _D_ to the right the weight _W■_ represented by _OT_ must be subtracted from _R_, so that the shear over the section _b_ of the span is _R_ - _W■_ or _QV_ in the diagram. Similarly, in passing the point _H_ toward the right, both _W■_ and _W■_ must be subtracted from _R_, giving the negative shear (the previous shear being taken positive) _VW_. The negative shear _VW_ remains constant throughout the distance _c_, but is increased by _W■_ at the point _L_, so that throughout the distance _d_ the shear _S■_ = _-R■_. These shear values are all shown in the lower portion of Fig. 13 by the vertical shaded lines. Obviously it is a matter of indifference whether the shear above the straight line _GJ_ is made positive or negative; it is only necessary to recognize that the signs are different.

In the case of heavy beams, either built or rolled, as in railroad structures, it is of the greatest importance to determine both the bending moments and the shears, as represented in the preceding equations and diagrams, and to provide sufficient metal to resist them.

The case of Fig. 13 is perfectly general for moments and shears, and the methods developed are applicable to any amount or any system of loading whatever.

=83. Bending Moments and Shears with Uniform Loads.=—Fig. 14 represents what is really a special case of Fig. 13, in which the loading is uniform for each unit of length of the beam throughout the whole span _l_. Inasmuch as the load is uniformly distributed, it is evident that the reaction at each end of the beam will be one half the total load, or

_wl_ _R = R_■ = ----. (17) 2

[Illustration: FIG. 14.]

The general expression for the bending moment at any point _G_ in the span, and located at the distance _x_ from the end _A_, will take the form

_x w_ _M_ = _Rx_ - _wx_.--- = --- _x_(l-_x_). (18) 2 2

This equation, giving the value of _M_, is the equation of a parabola with the vertex over the middle of the span. The bending moment at the latter point will be found by placing _x = l/2_ in equation (18), which will give

wl² _M_ = -----. (19) 8

Hence, in Fig. 14, if the vertical line _DC_ be erected at _D_, so as to represent the value of _M_ in equation (19) to a convenient scale, the parabola _ACB_ may be at once drawn. Any vertical intercept, as _GF_ between _AB_ and the curve _AFCB_, will represent by the same scale the bending moment in the beam at the point indicated by the intercept. Equation (19), giving the greatest external bending moment in a simple beam due to a uniform load, is constantly employed in structural work, and shows that that moment is equal to the total load multiplied by one eighth of the span.

It has already been shown, in connection with Fig. 12, that when a single centre weight rests on a beam the centre bending moment is equal to that weight multiplied by one fourth the span. If the total uniform load in the one case is equal to the single load in the other, these equations show that the single centre load will produce just double the bending moment due to the same load uniformly distributed over the span. Wherever it is feasible, therefore, the load should be distributed rather than concentrated at the centre of the span.

That portion of Fig. 14 shaded with vertical lines shows the shear existing in the beam. Evidently the shear at each end is equal to the reaction, or one half the total load on the span. The expression for the shear at any point, as _G_, distant _x_ from _A_ will be

(_l_) _S = R_ - _wx_ = _w_(---- - _x_). (20) (2)

If _x = l/2_ in equation (20), _S_ becomes equal to zero. In other words, there is no shear at the centre of the span of a beam uniformly loaded. Hence, if at each end of the span a vertical line _AK_ or _BL_ be laid off downward, and if straight lines _KD_ and _DL_ be drawn, any vertical intercept, as _GH_, between these lines and _AB_ will represent the shear at the corresponding point. Equation (20) also shows that the shear _S_ at any point is equal to the load resting on the beam between the centre _D_ and that point. Although this case of uniform loading is a special one it finds wide application in practical operations.

=84. Greatest Shear for Uniform Moving Load.=—The preceding loads have been treated as if they were occupying fixed positions on the beams considered. This is not always the case. Many of the most important problems in connection with the loading of beams and bridges arise under the supposition that the load is movable, like that of a passing railroad train. One of the simplest of these problems, although of much importance, consists in finding the location of a uniform moving load, like that of a train of cars, which will produce the greatest shear at a given point of a simple beam, such as that represented in Fig. 15, in which a moving load is supposed to pass continuously over the span from the left-hand end _A_. It is required to determine what position of this uniform load will produce the greatest shear at the section _C_.

[Illustration: FIG. 15.]

Let the moving load extend from _A_ to any point _D_ to the right of _C_. The two reactions _R_ and _R■_ may be found by the methods already indicated. Let _W_ represent the uniform load resting on the portion _CD_ of the span. The shear _S′_ existing at _C_ will be

_S■ = R■ - W_. (21)

Let _R■_ be that part of _R■_ which is due to _W_, and _R■_ that part due to the load on _AC_. Evidently _R■_ is less than _W_; then

_S■ = R■ + R■ - W_. (22)

Since the negative quantity _W_ is greater than the positive quantity _R■_, _S′_ will have its greatest value when both _W_ and _R■_ are zero. Hence the greatest shear at the point _C_ will exist when

_S■ = R■_. (23)

Obviously the loading must extend at least from _A_ to _C_ in order that _R■_ may have its maximum value. Hence _the greatest shear at any section will exist when the uniform load extends from the end of the span to that section, whatever may be the density of the load_.

If the segment of the span covered by the moving load is greater than one half the span, the maximum shear is called the _main shear_; but if that segment is less than one half the span, the maximum shear is called the _counter-shear_. The reason for these two names will be apparent later in the discussion of bridge-trusses.

This rule for determining the maximum shear at any section of a beam is equally applicable to bridge-trusses under certain conditions, and has an important bearing upon the determination of the greatest stresses in some of the members of bridge-frames, although it has less importance now than it had in the earlier days of bridge-building.

=85. Bending Moments and Shears for Cantilever Beams.=—The case of a loaded overhanging beam or cantilever bracket, as shown in Fig. 16, is sometimes found. In that figure a single weight _W_ is supposed to be applied at the end, while a uniform load _w_ per unit of length extends over its length _l_. The bending moment at any point _C_ distant _x_ from the end will obviously be

wx² _M = Wx_ + -----. (24) 2

[Illustration: FIG. 16.]

The greatest value of the bending moment will be found by placing _x_ equal to _l_ in equation (24), and it will have the value

wl² _M■ = Wl_ + -----. (25) 2

The shear at any point and at the end _A_ respectively will be

_S = W + wx_ and _S■ = W + wl_. (26)

The shear due to _W_ is equal to itself and is constant throughout the whole length of the beam.

The second term of the second member of equation (24) is the equation of a parabola with its vertex at _B_, Fig. 16. Hence if _AF_ be laid off equal to (_wl_²)/2, and if the parabola _FHB_ be drawn, any vertical intercept, as _HK_, between that curve and _AB_ will represent the bending moment at the corresponding point. On the other hand, the first term of the second member of equation (24) shows that the bending moment due to _W_ varies directly as the distance from _B_. Hence if _AG_ be laid off vertically downward from _A_ equal to _Wl_ to any convenient scale, then any intercept, as _KL_, between _AB_ and _BG_ will represent the bending moment due to _W_ at the corresponding point of the beam.

=86. Greatest Bending Moment with any System of Loading.=—One of the most important positions of loading to be established either for simple beams or for bridge-trusses is that at which any given system of loading whatever is to be placed on any span so as to produce the maximum bending moment at any prescribed point in that span. In order to make the case perfectly general a system of arbitrary loads, like that shown in Fig. 17, is assumed and the system is supposed to be a moving one.

[Illustration: FIG. 17.]

The separate loads are placed at fixed distances apart, indicated by the letters _a_, _b_, _c_, _d_, etc., _W_■ being supposed to be at the head of the train, while _W_ is the last load having a variable distance _x_ between it and the end of the span. In Fig. 17 this system of moving loads or train is supposed to pass over the span _l_ from right to left. The problem is to determine the position of the loading, so that the bending moment at the section _C_ of the beam or truss will be a maximum, the section _C_ being at the distance _l■_ from the left-hand end of the span. The complete analysis of this problem is comparatively simple and may readily be found, but it is not necessary for the accomplishment of the present purpose to give it here. In order to exhibit the formula which expresses the desired condition, let _W_■■ be that weight which is really placed at _C_, but which is assumed to be an indefinitely short distance to the left of that point, for a reason which will presently be explained. The equation of condition or criterion sought will then be the following:

_l■ W■ + W■ + ... + W■■_ ----- = ----------. (27) _l W■ + W■ + W■ + ... + W■_

If the loads are so placed as to fulfil the condition expressed in equation (27), the bending moment at section _C_ will be a maximum. If the variation in the train weights is very great, it is possible that there may be more than one position of the train which will satisfy that equation. It is necessary, therefore, frequently to try different positions of the loading by that criterion and then ascertain which of the resulting maximum moments is the greatest. It is not usually necessary to make more than one or two such trials. The application of the equation is therefore simple and involves but little labor.

It will usually happen that _W_■■ in equation (27) is not to be taken as the whole of that weight, but only so much of it as may be necessary to satisfy the equation. This is simply assuming that any weight, _W_, may be considered as made up of two separate weights placed indefinitely near to each other, which is permissible.

After having found the position of loading which satisfies equation (27), the resulting maximum bending moment will take the following form:

_l■_ _M■_ = ----- [_W■a_ + (_W■+ W■_)_b_ + ... + (_W■ + W■ + ... + W■_)_x_] _l_

- _W■a_ - (_W■ + W■_)_b_ - ... - (_W■ + W■ + ... + W■■■■■■_)(?). (28)

In this equation _x_ corresponds to the position of loading for maximum bending, while the sign (?) represents the distance between the concentrations _W_■■■■■■ and _W_■■. This equation has a very formidable appearance, but its composition is simple and it is constantly used in making computations for the design of railroad bridges. The loads _W_■, _W_■, _W_■, etc., represent the actual weights on the driving-axles and other axles of locomotives, tenders, and cars, and the spacings _a_, _b_, _c_, etc., are the actual spacings found between those axles. In other words, these quantities are the actual weights and dimensions of the different portions of moving railroad trains.

The computations indicated by equation (28) are not made anew in every instance. Concentrated weights of typical locomotives, tenders, and cars are prescribed by different railroad companies for their different classes of trains, ranging from the heaviest freight traffic to the lightest passenger train. A tabulation is then made from equation (28) for each such typical train, and it is used as frequently as is necessary to design a bridge to carry the prescribed traffic. The tabulations thus made are never changed for a given or prescribed loading.

=87. Applications to Rolled Beams.=—It is to be remembered that these last observations do not limit the use of equations (27) and (28) to railroad-bridge trusses only; they are equally applicable to solid and rolled beams and are frequently used in connection with their design. Great quantities of these beams and various rolled steel shapes are used in the construction of large modern city buildings, as well as in railroad and highway bridge structures. The steel frames of the great office buildings, so many of which are seen in New York and Chicago as well as in other cities, which carry the entire weight of the building, are formed wholly of these steel shapes. The so-called handbooks published by steel-producing companies exhibit the various shapes rolled in each mill. These books also give in tabular statements many numerical values of the moment of inertia, the section modulus, and other elements of all these sections, so that the formulæ which have been established in the preceding pages may be applied in practical work with great convenience and little labor. Tables are also given showing the sizes of rolled beams required to sustain the loads named in them. Such tables are formed for practical use, so that, knowing the distance apart of the beams, their span, and the load per square foot which they carry, the required size of beam may be selected without even computation. Such labor-saving tables are quite common at the present time, and they reduce greatly the labor of numerical computations.

CHAPTER VIII.

=88. The Truss Element or Triangle of Bracing.=—A number of the preceding formulæ find their applications to bridge-trusses, as well as to beams; hence it is necessary to give attention at least to some simple forms of those trusses.

[Illustration: FIG. 18.]

[Illustration: FIG. 18_a_.]

The skeleton of every bridge-truss properly designed to carry its load is an assemblage of triangles. In other words, the truss element, i.e., the simplest possible truss, is the triangular frame, such as is shown in skeleton in Figs. 18 and 18_a_. These simple triangular frames are sometimes called the King-post Truss. The action of such a triangular frame in carrying a vertical load is

extremely simple. In Fig. 18 let the weight _W_ be suspended from the apex _C_ of the triangle. The line _CF_ represents that weight, and if the latter be resolved into its two components parallel to the two upper members of the triangular frame, the two component forces _CG_ and _CD_ will result. If from _D_ and _G_ the horizontal lines _DH_ and _GO_ be drawn, those two lines will represent the horizontal components of the forces or stresses in the two bars _CA_ and _CB_. The force _HD_ will act to the left at the point _A_, and the force _CG_ will act to the right at _B_, and as these two forces are equal and opposite to each other, equilibrium will result. Either of the horizontal forces will represent the magnitude of the tension in _AB_. Both _AC_ and _CB_ will be in compression, the former being compressed by the force _CD_, and the latter by the force _CG_. The manner of drawing a parallelogram of forces makes the triangle _COG_ similar to _CNB_, and _CHD_ similar to _CNA_; hence _HW_ divided by _CH_ will be equal to _AN_ divided by _NB_. But _HW_ is the vertical component of the stress in _CB_, while _CH_ is the vertical component of the stress in _AC_, the latter being represented by the reaction _R_ and the former by the reaction _R′_. It is seen, therefore, that the weight _W_ is carried by the frame to the two abutment supports _A_ and _B_, precisely as if it were a solid beam. In other words, the important principle is established that when weights rest upon a simple truss supported at each end they will produce reactions at the ends in accordance with the principle of the lever, precisely as in the case of a solid beam. In engineering parlance it is stated that the weight _W_ is divided according to the principle of the lever, and that each portion travels to its proper abutment through the members of the triangular frame. If the two inclined members of the triangular frame are equally inclined to a vertical, the case of Fig. 18_a_ results, in which one half of the weight goes to each abutment.

The triangular frame, with equally inclined sides, shown in Fig. 18_a_, is evidently the simplest form of roof-truss, constituting two equally inclined members with a horizontal tie.

=89. Simple Trusses.=—The simplest forms of trussing used for bridge purposes are those shown in Figs. 19, 20, and 21. There are many other forms which are exhibited in complete treatises on bridge structures, but these three are as simple as any, and they have been far more used than any other types. The horizontal members _af_ and _AB_ are called the “chords,” the former being the upper chord and the latter the lower chord. The vertical and inclined members connecting the two chords are called the web members or braces. When a bridge is loaded, either by its own weight only, or by its own weight added to that of a moving train of cars, the upper chord will evidently be in compression, while the lower chord is in tension. A portion, which may be called a half, of the web members will be in tension and the other portion, or half, will be in compression.

The function of the upper and lower chords is to take up or resist the horizontal tension and compression which correspond to the direct stresses of tension and compression existing in the longitudinal fibres of a loaded solid or flanged beam. The metal designed to take these so-called direct stresses is concentrated in the chords of trusses, whereas it is distributed throughout the entire section of a beam, whether that beam be solid or flanged. The function of the web members of a truss is to resist the transverse or vertical shear which is represented by the algebraic sum of the reactions and loads. The total section of a solid beam resists these vertical shears, while the web only of a flanged beam is estimated to perform that duty. The horizontal shears, which have already been recognized as existing along the horizontal planes in a bent beam, are resisted by the inclined web members of a truss, the horizontal stress components being the horizontal shears, whereas the vertical shears are resisted by the vertical web members of a truss. If the web members are all inclined, as shown in Fig. 21, each web member resists both horizontal and vertical shear. It is thus seen that the members of a truss perform precisely the same duties as the various portions of either solid or flanged beams. Inasmuch as the chords of bridge-trusses resist the direct or horizontal stresses of tension and compression produced by the bending in the truss, it is obvious that the greatest chord stresses will be found at the centre of the span, and that they will be the smallest at the ends of the span. In the web members, on the contrary, since the vertical shear is the greatest at the ends of the span and equal to the reactions at those points, decreasing towards the centre precisely as in solid beams, the greatest web stresses will be found at the ends of the span and the least near the centre. It is obvious that the areas of cross-sections of either chords or web members must be proportioned to the stresses which they carry. Hence the distribution of stresses just described tends to a uniform distribution of the truss weights over the span.

=90. The Pratt Truss Type.=—In the discussion of these three simple types of trusses, the simplest possible loading of a perfectly uniform train will be assumed. The portions into which the trusses are divided by the vertical or inclined bracing are called panels. In Fig. 19, for instance, the points 1, 2, 3, 4, 5, and 6 of the lower chord and _a_, _b_, _c_, _d_, _e_, and _f_ of the upper chord are called panel-points. The distance between each consecutive two of these points is called a panel length. The uniform train-load which is to be assumed will be represented by the weight _W_ at each panel-point. This is called the “moving load” or “live load.” The own weight of the structure is called the “dead load” or the “fixed load.” The dead load per upper-chord panel will be taken as _W■_, and _W_■ for the lower chord. The loads to be used will, therefore, be as follows:

Panel moving load = _W_; Upper-chord panel dead load = _W■_; Lower ” ” ” = _W_■.

There will also be used the length of panel and depth of truss as follows:

Panel length = _p_; Depth of truss = _d_.

In these simple trusses with horizontal upper and lower chords the stress in any inclined web members is equal to the shear multiplied by the secant of the inclination of the members to a vertical line. Also, at each panel-point every inclined web member, in passing from the end to the centre of the span, adds to either chord stress at that point an amount represented by the horizontal component of the stress which it carries; or, what is the same thing, an amount equal to the shear at the panel in question multiplied by the tangent of its angle of inclination to a vertical line.

It has already been shown in discussing solid beams that the greatest shear at any section will be found when the uniform moving load covers one of the segments of the span. This principle holds equally true for trusses carrying uniform panel-loads like those under consideration. In determining the stresses in these trusses, therefore, the inclined web members will take their greatest stresses when the moving train or load extends from the farthest end of the span up to the foot of the member in question. In this connection it is to be observed also that any two web members meeting in the chord which does not carry the moving load take their greatest stresses for the same position of the latter. The so-called “counter web members” take no stresses from the dead load.

Inasmuch as every load placed upon a truss will produce compression in the upper chord and tension in the lower, the greatest chord stresses will obviously exist when the moving load covers the entire span, and that condition of loading is to be used for the stresses in the following cases.

Bearing these general observations in mind, the ordinary simple method of truss analysis yields the tabulated statement of stresses given below for the three types selected for consideration. The first case to be treated is that of Fig. 19, which represents the Pratt truss type. The moving load is supposed to pass across the bridge from right to left. The plus sign indicates tension and the minus sign compression.

[Illustration: FIG. 19.]

Stress in c■ = + (¹/■ + ²/■) _W_ sec _a_ = ³/■ _W_ sec _a_. _Stress in T■_ = + (¹/■ + ²/■ + ³/■) _W_ sec _a_ = ■/■ _W_ sec _a_; ” ” _T■_ = + [(¹/■ + ²/■ + ³/■ + ■/■) _W_ + _W■_ + _W■_] sec _a_ = (¹■/■ _W_ + _W■_ + _W■_) sec _a_; ” ” _T■_ = + [(¹/■ + ²/■ + ³/■ + ■/■ + ■/■) _W_ + _2w■_ + _2w■_] sec _a_ = (¹■/■ W + 2w■ + 2w■) sec _a_; ” ” _T■_ = + (_W_ + _W■_).

Stress in P■ = -(■/■ _W_ + _W■_); ” ” _P■_ = -(¹■/■ _W_ + 2_W■_ + _W■_); ” ” _P■_ = -3(_W_ + _W■_ + _W■_) sec _a_.

Stress in L■ =_Stress in L■_ = + 3(_W_ + _W■_ + _W■_) tan _a_; ” ” _L■_ = ” ” _L■_ + 2(_W_ + _W■_ + _W■_)tan _a_ + + 5(_W_ + _W■_ + _W■_) tan _a_; ” ” _L■_ = ” ” _L■_ + (_W_ + _W■_ + _W■_) tan _a_ + 6(_W_ + _W■_ + _W■_) tan _a_.

Stress in U■ = _-Stress in L■_ = -5(_W_ + _W■_ + _W■_) tan α; ” ” _U■_ = - ” ” _L■_ = -6(_W_ + _W■_ + _W■_) tan α; ” ” _U■_ = ” ” _U■_ = -6(_W_ + _W■_ + _W■_) tan α.

It is easy to check any of the chord stresses by the method of moments. As an example, let moments first be taken about the panel-point 5 in the lower chord, and then about the panel-point _c_ in the upper chord. The following expressions for the chord members _U■_ and _L■_ will be found, and it will be noticed that they are identical with the stresses for the same members given in the preceding tabulation, the counter-members, shown in broken lines, being omitted from consideration as they are not needed.

_R.2p_ - (_W + W■ + W■_)_p_ _Stress in U■_ = ---------- _d_

_p_ = 5(_W + W■ + W■_) ---- = 5(_W + W■ + W■_) tan α. (29) _d_

_R.3p_ - 2(_W + W■ + W■_) . 1½_p_ _Stress in L■_ = ---------- _d_

= 6(_W + W■ + W■_) tan α. (30)

[Illustration: FIG. 20.]

=91. The Howe Truss Type.=—The truss shown in Fig. 20 is the skeleton of the Howe truss, to which reference has already been made. The inclined web members are all in compression, while the vertical web members are all in tension. In the Howe truss all compression members are composed of timber. It has the disadvantage of subjecting the longest web members to compression. It thus makes the truss, if built all in iron or steel, heavier and more expensive than the trusses of the Pratt type. As in the preceding case, the moving train or load is supposed to pass across the bridge from _B_ to _A_. Also, as before, the + sign indicates tension and the - sign compression. The greatest stresses, given in the tabulated statement below, can be computed or checked by the method of moments in this case, precisely as in the preceding.

Stress in c■ = -(¹/■ + ²/■) _W_ sec _a_ = -³/■ _W_ sec _a_.

Stress in P■ = -(¹/■ + ²/■ + ³/■) _W_ sec _a_ = -■/■ _W_ sec _a_; ” ” P■_ = -(_¹■/■ W + W■ + W■_) sec _a_; ” ” P■_ = -(_¹■/■ W + 2W■ + 2W■_) sec _a_; ” ” P■_ = -3(_W + W■ + W■_) sec _a_.

Stress in T■ = + (_¹■/■ W + W■_) sec _a_; ” ” T■_ = + (_¹■/■ W + W■ + 2W■_) sec _a_; ” ” T■_ = + (_3W + 2W■ + 3W■_) sec _a_.

Stress in L■ = + 3(_W + W■ +W■_) tan _a_; ” ” L■_ = + 3(_W + W■ + W■_) tan _a_+2(_W + W■ + W■_) tan _a_ = + 5(_W + W■ + W■_) tan _a_; ” ” L■_ = + 5(_W + W■ + W■_) tan _a_+(_W + W■ + W■_) tan _a_ = + 6(_W + W■ + W■_) tan _a_; ” ” L■_ = _Stress in L■._

Stress in U■ = _- Stress in L■_ ” ” U■_ = _- ” ” L■_; ” ” U■_ = _- ” ” L■_.

It will be noticed in the cases of Figs. 19 and 20 that upper and lower chord panels in the same lozenge or oblique panel have identically the same stresses, but with opposite signs. For instance, in Fig. 20 the stress in _U■_ is equal in amount to that in _L■_; and the same observation can be made in reference to the stresses in _U■_ and _L■_ of Fig. 19. This must necessarily always be the case in trusses having vertical web members.

In making computations for these forms of trusses it is very essential to observe where the first counter-member, as _c■_, must be used. These counter-members may be omitted if the proper main web members near the centre of the span are designed to take both tension and compression.

=92. The Simple Triangular Truss.=—The truss shown in Fig. 21, in which all the web members have equal inclination to a vertical line, is sometimes called the Warren Truss, although that term has also been applied specially to this type of truss so proportioned as to make the depth just equal to the panel length. As before, the moving train is supposed to pass over the bridge from _B_ toward _A_, while the + sign represents tension and the - sign compression. The greatest stresses are the following.

[Illustration: FIG. 21.]

{ -(_■/■W + ½W■_) sec _a_, or _Stress in P■_ = { +(_■/■W - ½W′_) sec _a_; ” ” P■_ = { -(_¹■/■W + 1½W′ + W■_) sec _a_, or { +(_³/■ W - 1½W■ - W■_) sec _a_;

” ” P■_ = -(_¹■/■ W + 2½W■ + 2W■_) sec _a_; ” ” P■_ = -(_3W + 3½ W■ + 3W■_) sec _a_.

{ +(_¹■/■W + ½W■ + W■_) sec _a_, or _Stress in T■_ = { -(_³/■W - ½W■ - W■_) sec _a_;

” ” T■_ = +(_¹■/■W + 1½W′ + 2W■_) sec _a_; ” ” T■_ = +(_3W + 2½W■ + 3W■_) sec _a_.

Stress in L■ = + 3(_W + W■ + W■_) tan _a + ½W′_ tan _a_; ” ” L■_ = _Stress in L■_ + (_5W + 5W■ + 5W■_) tan _a_ = + 8(_W + W■ + W■_) tan _a + ½W■_ tan _a_; ” ” L■_ = _Stress in L■_ + 3(_W + W■ + W■_) tan _a_ = + 11 (_W + W■ + W■_) tan _a + ½W■_ tan _a_; ” ” L■_ = _Stress in L■_ + (_W + W■ + W■_) tan _a_ = + 12 (_W + W■ + W■_) tan _a + ½W■_ tan _a_.

Stress in U■ = -6(_W + W■ + W■_) tan _a_; ” ” U■_ = -6(_W + W■ + W■_)tan _a_ - 4(_W + W■ + W■_) tan _a_ = -10(_W + W■ + W■_) tan _a_;

” ” U■_ = -10(_W+ W■+ W■_) tan _a_ - 2(_W + W■ + W■_) tan _a_ = -12(_W + W■ + W■_) tan _a_.

The chord stresses may be checked or found by the method of moments, precisely as in the case of Fig. 19. If, for instance, it is desired to determine the stresses in the upper chord member _U■_, moments must be taken about the lower-chord panel-point 5, and about the upper-chord panel-point _d_ for the lower-chord stress in _L■_. Taking moments about those points, results given in

equations (31) and (32) will at once follow, which it will be observed are identical with the values previously found for the same members.

(_3W + 3½ W′ + 3W■_)._2p_ - 2_W′p_ - (_W + W■_)_p_ _Stress in U■_ = - ---------- _d_

= -10(_W + W′ + W■_) tan _a_. (31)

(_3W + 3½ W′ + 3W■_)._3½ p_ - 3(_W + W■_)._1½p - 3W′.2p_ _Stress in L■_ = + ---------- _d_

= + 12(_W + W■ + W′_) tan _a_ + ½_W′_ tan _a_. (32)

=93. Through- and Deck-Bridges.=—These simple trusses have all been taken as belonging to the “through” type, i.e., the moving load passes along their lower chords. It is quite common to have the moving load pass along the upper chords, in which cases the bridges are said to be “deck” structures. The general methods of computation are precisely the same whether the trusses be deck or through. It is only necessary carefully to observe that the application of the methods of analysis depends upon the position of each panel-load as it passes across the structure.

[Illustration: Fig. 22.]

=94. Multiple Systems of Triangulation.=—Figs. 19, 20, and 21 exhibit what are called single systems of triangulation or single systems of bracing, but in each of those types the system of web members may be double or triple; in other words, they may be manifold. There have been many bridges built in which two or more systems of bracing are employed. Fig. 22 represents a truss with a double system of triangulation, known at one time as the Whipple truss. Fig. 23, again, exhibits a quadruple system of triangulation with all inclined web members. The method of computation for such manifold systems is precisely the same as for a single system, each system in the compound truss being treated as carrying those loads only which rest at its panel-points. This procedure is not quite accurate. The complete consideration of an exact method of computation would take the treatment into a region of rather complicated analysis beyond the purposes of these lectures, but its outlines will be set forth on a later page. The exact method of treatment of two or more web systems involves the elastic properties of the material of which the trusses are composed. In the best modern bridge practice engineers prefer to design trusses of all lengths with single web systems, although the panels are frequently subdivided to avoid stringers and floor-beams of too great weight.

[Illustration: Fig. 23.]

=95. Influence of Mill and Shop Capacity on Length of Span.=—In the early years of iron and steel bridge-building the sizes of individual members were limited by the shop capacity for handling and manufacturing, and by the relatively small dimensions of bars of various shapes, and of plates which could be produced by rolling-mills. As both mill and shop processes have advanced and their capacities increased, corresponding progress has been made in bridge design. Civil engineers have availed themselves of those advances, so that at the present time single system trusses with depths as great as 85 feet or more and spans of over 550 feet are not considered specially remarkable.

=96. Trusses with Broken or Inclined Chords.=—As the lengths of spans have increased certain substantial advantages have been gained in design by no longer making the upper chords horizontal in the case of long through-spans, or indeed in the cases of through-spans of moderate length. The greatest bending moments and the greatest chord stresses have been shown to exist at the centre of the span, while the greatest web stresses are found near the ends. Trusses may be lightened in view of those considerations by making their depths less at the ends than at the centre. This not only decreases the sectional areas of the heaviest web members near the ends of the truss, but also shortens them. It adds somewhat to the sectional area of the end upper-chord members, but the resultant effect is a decrease in total weight of material and increased stability against wind pressure by the decreased height and less exposure near the ends. It has therefore come to be the ruling practice at the present time to make through-trusses with inclined upper chords for practically all spans from about 200 feet upward. A skeleton diagram of such a truss is given in Fig. 24.

[Illustration: Fig. 24.]

=97. Position of any Moving Load for Greatest Web Stress.=—In the preceding treatment of bridge-trusses with parallel and horizontal chords a moving or live load has been taken as a series of uniform weights concentrated at the panel-points. This simple procedure was formerly generally used, and at the present time it is occasionally employed, but it is now almost universal practice to assume for railroad bridges a moving load consisting of a series of concentrations, which represent both in amount and

distribution the weights on the axles of an actual railroad train. If a bridge is supposed to be traversed by such a train, it becomes necessary to determine a method for ascertaining the positions of the train causing the greatest stresses in the various members of the bridge-truss. The mathematical demonstration of the formulæ determining those positions of loading need not be given here, but it can be found in almost any standard work on bridges.

In order to show concisely the results of such a demonstration let it be desired to find the position of a moving load which will give the greatest stress to any web member, as _S_ in Fig. 24. Let the point of intersection of _GK_ and _DC_ be found in the point _O_, then let _CK_ be extended, and on its extension let the perpendicular _h_ be dropped from _O_. The distance of the point _O_ from _A_, the end of the span, is _i_, while _m_ is the distance _AD_. Using the same notation which has been employed in the discussion of beams, together with that shown in Fig. 24, equation (33) expresses the condition to be fulfilled by the train-loads in order that _S_ shall have its greatest stress. The first parenthesis in the second member of that equation represents the load between the panel _p_ and the left end of the span, while the second parenthesis represents the load in panel _p_ itself.

_l_ _W■ + W■ + ... + W■_ = - ----(_W■ + W■_ + etc.) _i_

_l_(_m + i_) + (_W■ + W■_ + etc.) ---------- (33) _pi_.

It will be noticed in equation (33) that the quantity _m_ shows in what panel the inclined web member whose greatest stress is desired is located, and it is important to observe that panel carefully. If, for instance, the vertical member _KD_ were in question, the point _O_ would be located at the intersection of the panel _NK_ and the lower chord of the bridge. In other words, the point _O_ must be at the intersection of the two chord members belonging to the same panel in which the web member is located.

=98. Application of Criterions for both Chord and Web Stresses.=—The criterion, equation (33), belongs to web members only. If it is desired to find the position of moving load which will give the greatest chord stresses in any panel, equation (27), already established for beams, is to be used precisely as it stands, the quantity _l′_ representing the distance from one end of the span to the panel-point about which moments are taken.

If the desired positions of the moving load for greatest stresses have been found by equations (27) and (33), those stresses themselves are readily found by taking moments about panel-points for chord members and about the intersection-points _O_, Fig. 24, for web members. These operations are simple in character and are performed with great facility. Tabulations and diagrams are made for given systems of loading by which these computations are much shortened and which enable the numerical work of any special case to be performed quickly and with little liability to error. These tabulations and diagrams and other shortening processes may be found set forth in detail in many publications and works on bridge structures. They constitute a part of the office outfit of civil engineers engaged in structural work.

The criterion, equation (27), for the greatest bending moments in a bridge is applicable to any truss whatever, whether the chords are parallel or inclined, but it is not so with equation (33). If the chords of the trusses are parallel, the quantity _i_ in equation (33) becomes infinitely great, and the equation takes the following form:

_l_ _W■ + W■ + ... + W■_ = ---- (_W■ + W■_ + etc.) (34) _p_

Ordinarily the span _l_ divided by the panel length _p_ is equal to the number of panels in the span. Hence equation (34) shows, in the case of parallel or horizontal chords, that when the moving load is placed for the greatest web stress in any panel, the total load on the bridge is equal to the load in that panel multiplied by the total number of panels.

=99. Influence Lines.=—A graphical method, known as that of “influence lines,” is used for determining the greatest shears and bending moments caused by a train of concentrated weights passing along a beam or bridge-truss. Obviously it must express in essence that which has already been shown by the formulæ which determine positions of moving loads for the greatest shears and bending moments. In reality it is the application of graphical methods which have become so popular to the determination of the greatest stresses in beams and bridges.

=100. Influence Lines for Moments both for Beams and Trusses.=—It is convenient to construct these influence lines for an arbitrary load which may be considered a unit load; the effect of any other load will then be in proportion to its magnitude. The results determined from influence lines drawn for a load which may be considered a unit can, therefore, be made available for other loads by multiplying the former by the ratio between any desired load and that for which the influence lines are found.

[Illustration: FIG. 25.—Bending Moment in a Simple Beam.]

_AB_ in Fig. 25 represents a beam simply supported at each end, so that any load _g_ resting upon it will be divided between the points of support, according to the law of the lever. Let it be desired to determine the bending moment at the section _X_ produced by the load _g_ in all of its positions as it passes across the span from _A_ to _B_. Two expressions for the bending moment must be written, one for the load _g_ at any point in _AX_, and the other for the load at any point in _BX_. The expression for the first bending moment is

_z_ _M = g_ ----(_l-x_), (_a_) _l_

and that for the latter

_l-z_ _M′ = g_ ---- _x_. (_b_) _l_

As shown in the figure, _z_ and _x_, the latter locating the section at which the bending moments are to be found, are measured to the right from _A_. Equation (_a_) shows that if the quantity _g_(l-_x_) be laid off, by any convenient scale, as _BK_ at right angles to _AB_, _XC_ will represent the moment _M_ by the same scale when _x = z_ or when _z_ has any value between 0 and _x_. Similarly will _AD_ be laid off at right angles to _AB_ by the same scale as before, to represent _gx_. Then when _x = z_ the expression for _M′_ will have the same value _XC_ as before. Hence if the lines _AC_ and _CB_ be drawn as parts of _AK_ and _DB_, any vertical intercept between _AB_ and _ACB_ will represent the bending at _X_ produced by the load _g_ when placed at the point from which the intercept is drawn. The lines _AC_ and _CB_ are the influence lines for the bending moments produced by the load _g_ in its passage across the span _AB_. It is to be observed that the influence lines are continuous only when the positions of the moving load are consecutive. In case those positions are not consecutive the influence lines are polygonal in form.

If there are a number of loads _g_ resting on the span at the same time, the total bending moments produced at _X_ will be found by taking the sum of all the vertical intercepts between _AB_ and _ACB_, drawn at the various points where those loads rest. The influence lines drawn for a single load, therefore, may be at once used for any number of loads.

The load _g_ is considered as a unit load. If the vertical intercepts representing the bending moments by the scale used are themselves represented by _y_, and if _W_ represent any load whatever, the general expression for the bending moment at _X_, produced by any system of loads, will be

_l_ ---- Σ_Wy._ (_c_) _g_

If this expression be written as a series, the general value of the bending moment will be the following:

_l_ _M_ = --- (_W■y■ + W■y■ + W■y■_ + etc.). (_d_) _g_

The effect of a moving train upon the bending moment at any given section is thus easily made apparent by means of influence lines. It is obvious that there will be as many influence lines to be drawn as there are sections to be considered. In the case of a truss-bridge there will be such a section at every panel-point.

A slight modification of the preceding results is to be made when the loads are applied to the beam or truss at panel-points only.

In Fig. 25 let 1, 2, 3, 4, 5, 6, and 7 be panel-points at which loads are applied, and let the load _g_ be located at the distance _z′_ to the right of panel-point 5, also let the panel length be _p_. The reactions at 5 and 6 will then be

_p-z′_ _z′_ _R■ = g_ -------- and _R■ = g_ ------. _p_ _p_

The reactions at _A_ will then be

_l-z_ _R = g_ ------. _l_

Hence the moment at any section _X_ in the panel in question will be

[_l-x z′_] _M = Rx-R■_{_z_′-(_z-x_)} = _g_[---- _z_-(_z-z′ + p-x_)---]. (_e_) [_l p_]

Remembering that _z-z′_ is a constant quantity, it is at once clear that the preceding expression is the equation of a straight line, with _M_ and _z_ or _z′_ the variables. If _z′ = 0_, equation (_e_) becomes identical with equation (_a_), while if _z′ = p_, it becomes identical with equation (_b_). Hence the influence line for the panel in which the load is placed, as 5-6, is the straight line _KL_. It is manifest that when the load _g_ is in any other panel than that in which the section _X_ is located, the effect of the two

reactions at the extremities of that panel will be precisely the same at the section as the weight itself acting along its own line of action. Hence the two portions _AK_ and _BL_ of the influence line are to be constructed as if the load were applied directly to the beam or truss, and in the manner already shown. The complete influence line will then be _AKLB_, and it shows that the existence of the panel slightly reduces the bending at any section within its limits. The panel 5-6, as treated, is that of a beam in which the bending moment will, in general, vary from point to point. If _AB_ were a truss, however, _X_ would always be taken at a panel-point, and no intercept between panel-points, as 5 and 6, would be considered.

=101. Influence Lines for Shears both for Beams and Trusses.=—The influence lines for shears in a simple beam, supported at each end, can be drawn in the manner shown in Fig. 25_a_. In that figure _AB_ represents a non-continuous beam with span _l_ supported from _A_. The reaction at _A_ will be

_l-z_ _R_ = ----- _g_. _l_

[Illustration: FIG. 25_a_.—Shear in a Simple Beam.]

Let _X_ be the section at which the shear for various positions of _g_ is to be found. When _g_ is placed at any point between _A_ and _X_ the shear _S_ at the latter point will be

_z_ _S_ = _R_ = _g_ = -_g_ ----; (_f_) _l_

but when the load is placed between _B_ and _X_ the shear becomes

_z_ _S_′ = _R_ = _g-g_ ----. (_h_) _l_

Obviously these two values of the shear are equations of two parallel straight lines, that represented by equation (_f_) passing through _A_, and that represented by equation (_h_) passing through _B_, the constant vertical distance between them being _g_. Hence let _BF_ be laid off negatively downward and _AG_ positively upward, each being equal to _g_ by any convenient scale. The ordinates drawn from the various positions 1, 2, 3 ... 6 of _g_ on _AB_ to _AD_ and _BC_ will be the shears at _X_ produced by the load _g_ at any point of the span, and determined by equations (_f_) and (_h_). The influence line, therefore, for the section _X_ will be the broken line _ADCB_. When _g_ is at _X_ the sign of the shear changes, since the latter passes through a zero value.

If a train of weights _W■_, _W■_, _W■_, etc., passes across the span, the total shear at _X_ will be found by taking the sum of the vertical intercepts between _AB_ and _ADCB_, drawn at the positions occupied by the various single weights of the train. If those single weights are expressed in terms of the unit load _g_, the shear _S_ will have the value

1 _S_ = ---- ∑ _Wy_; _g_

_y_ being the general value of the intercept between _AB_ and the influence line. The latter shows that the greatest negative shear at _X_ will exist when the greatest possible amount of loading is placed on _AX_ only, while the greatest positive shear at the same section will exist when _BX_ only is loaded. If _BX_ is the smaller segment of span, the latter shear is called the “counter-shear,” and the former the “main shear.”

If the loads are applied at panel-points of the span only, the treatment is the same in general character as that employed for bending moments. In Fig. 25_a_ let 4 and 5 be the panel-points between which the load _g_ is found, and let the panel length be _p_. Also, let _z′_ be the distance of the weight _g_ from panel-point 4. The reactions at _A_ and 4 will then be

_l - z p - z′_ _R_ = ------_g_ and _R■_ = ---------- _g_. _l p_

The shear at the section _X_ for any position of the weight _g_ will then be

(_z′ z_) _S_ = _R - R■_ = _g_(--- - ---). (_k_) (_p l_)

As this is the equation of a straight line, with _S_ and _z_ or _z′_ for the coordinates, the influence line for the panel in which the section _X_ is located will be the straight line represented by _KL_ in Fig. 25_a_.

If _z′_ is placed equal to 0 and _p_ successively, then will equation (_k_) become identical with equations (_f_) and (_h_) in succession. The shears at points 4 and 5 will therefore take the same values as if the loads were applied directly to the beam. For the reasons stated in connection with the consideration of bending moments, loads in other panels than that containing the section

for which the influence line is drawn will have the same effect on that section as if they were applied directly to the beam or truss. Hence _AKLB_ is the complete influence line for this case.

It is evident that there must be as many influence lines drawn as there are sections to be discussed. Also, if _g_ is taken as some convenient unit, i.e., 1000 or 10,000 pounds, it is clear that the labors of computation will be much reduced.

=102. Application of Influence-line Method to Trusses.=—In considering both the bending moments and shears when the loads are applied at panel-points, it has been assumed, as would be the case in an ordinary beam, that the bending moments as well as the shears may vary in the panel; but this latter condition does not hold in a bridge-truss. Neither bending moment nor shear varies in any one panel. Yet the influence lines for moments and shears are to be drawn precisely as shown in Figs. 25 and 25_a_. The section _X_ will always be found at a panel-point, and no intercept drawn within the limits of the panel adjacent to that section carrying the load _g_ is to be used. This method will be illustrated by the aid of Fig. 25_b_.

The employment of influence lines may be illustrated by determining the moment and shear in a single section of the truss shown in Fig. 24, which is reproduced in Fig. 25_c_, when carrying the moving load exhibited in Fig. 25_b_, although its use may be much extended beyond this simple procedure.

The moving load shown in Fig. 25_b_ is that of a railroad train consisting of a uniform train-load of 4000 pounds per linear foot drawn by two locomotives with the wheel concentrations shown; it is a train-load frequently used in the design of the heaviest class of railroad structures. If the criterion of equation (27) be applied to this moving load, passing along the truss shown in Fig. 25_c_, from left to right, it will be found that the greatest bending moment is produced at the section _Q_ when the second driving-axle of the second locomotive is placed at the truss section in question, as shown in Fig. 25_c_.

The unit load to be used in connection with the influence lines will be taken at 10,000 pounds. Remembering that the panel lengths are each 30 feet, it will be seen that the panel-point _Q_ is 150 feet from _A_. Hence the product _gx_ will be 1,500,000 foot-pounds. Similarly the product _g_(l - _x_) will be 900,000 foot-pounds. Laying off the first of these quantities, as _AD_, at a scale of 1,000,000 foot-pounds per linear inch, and the second quantity, as _BK_, by the same scale, the influence line _ACB_ can at once be completed. Vertical lines are next to be drawn through the positions of the various weights, including one through the centre of the uniform train-load 110 feet in length resting on the truss. The vertical line through the centre of the uniform train-load is shown at _O_. By carefully scaling the vertical intercepts between _AB_ and _ACB_, and remembering that each of the loads on the truss must be divided by 10,000, the following tabulated statement will be obtained, the sum of the intercepts for each set of equal weights being added into one item, and all the items of intercepts being multiplied by 1,000,000:

.195 × 110 × .4 × 1,000,000 = 8,580,000 foot-pounds. 1.78 × 2.6 × ” = 4,628,000 ” ” 2.14 × 4 × ” = 8,560,000 ” ” .485 × 2 × ” = 970,000 ” ” 1.525 × 2.6 × ” = 3,965,000 ” ” .9 × 4 × ” = 3,600,000 ” ” .12 × 2 × ” = 240,000 ” ” ---------- 2■30,543,000 ” ” ---------- Moment for one truss = 15,271,500 ” ”

The lever-arm of _ef_, i.e., the normal distance from _Q_ to _ef_, is 39.7 feet. Hence the stress in _ef_ is

15,271,500 ---------- = 384,700 pounds. 39.7

All the chord stresses can obviously be found in the same manner.

In order to place the same moving load so as to produce the greatest shear at the same section _Q_, the criterion of equation (33) must be employed. The dimensions of the truss shown in connection with Fig. 29 give the following data to be used in that equation: _i_ = 210 feet, _m_ = 60 feet, and _p_ = 30 feet.

_l_(_m + i_) _l_ Hence ---------- = 10^2/■, --- = 1^1/■. _pi i_

[Illustration: FIG. 25_b_.]

[Illustration: FIG. 25_c_.]

[Illustration: FIG. 25_d_.]

Introducing these quantities into equation (33), and remembering that the train moves on to the bridge from _A_, it would be found that the second axle of the first locomotive must be placed at the section _Q_, as shown in Fig. 25_d_, which exhibits the lower-chord panel-points numbered from 1 to 7. The conventional unit load _g_ will be taken in this case at 20,000 pounds. It is

represented as _AG_ and _BF_ (Fig. 25_d_), laid off at a scale of 10,000 pounds per inch. _K_ is immediately under panel-point 5 and _L_ is immediately above panel-point 6, hence the broken line _AKLB_ is the influence line desired. The vertical lines are then drawn from each train concentration in its proper position, all as shown, including the vertical line through the centre of the 54 feet of uniform train-load on the left. The summation of all the vertical intercepts between _AB_ and the influence line _AKL_, having regard to the scale and to the ratio between the various loads and the unit load _g_, will give the following tabular statement:

.22 × 54 × .2 × 10,000 = 23,760 pounds. 2.2 × 1.3 × ” = 28,600 ” 3.02 × 2 × ” = 60,400 ” .9 × 1 × ” = 9,000 ” 4.06 × 1.3 × ” = 53,780 ” 4.53 × 2 × ” = 90,060 ” .5 × 1 × ” = 5,000 ” -------- 2■ 270,600 ” -------- Shear for one truss = 135,300 ”

These simple operations illustrate the main principles of the method of influence lines from which numerous and useful extensions may be made.

CHAPTER IX.

=103. Lateral Wind Pressure on Trusses.=—The duties of a bridge structure are not confined entirely to the supporting of vertical loads. There are some horizontal or lateral loads of considerable magnitude which must be resisted; these are the wind loads resulting from wind pressure against both structure and moving train. In order to determine the magnitudes of these loads it is assumed in the first place that the direction of the wind is practically or exactly at right angles to the planes of the trusses and the sides of the cars. This assumption is essentially correct. There is probably nothing else so variable as both the direction and pressure of the wind. These variations are not so apparent in the exposure of our bodies to the wind, for the reason that we cannot readily appreciate even considerable changes either in direction or pressure. As a matter of fact suitable measuring apparatus shows that there is nothing steady or continued in connection with the wind unless it be its incessant variability. Its direction may be either horizontal or inclined, or even vertical, while within a few seconds its pressure may vary between wide limits. Under such circumstances the wind is as likely to blow directly against both bridge and train as in any other direction, and inasmuch as such a condition would subject the structure to its most severe duty against lateral forces, it is only safe and proper that the assumption should be made. The open work of bridge-trusses enables the wind to exert practically its full pressure against both trusses of a single-track bridge, or against even three trusses if they are used for a double-track structure. Hence it is customary to take the exposed surface of bridge-trusses as the total projected area on a plane throughout the bridge axis of both trusses if there are two, or of three trusses if there are three. Inasmuch as the floor of a bridge from its lowest point to the top of the rails or other highest point of the floor is practically closed against the passage of the wind, all that surface between the lowest point and the top of the rail or highest floor-member is considered area on which wind pressure may act.

Many experimental observations show that on large surfaces, greater perhaps than 400 or 500 square feet in area, the pressure of the wind seldom exceeds 20 or 25 pounds per square foot, while it may reach 80 or 90 pounds, or possibly more on small surfaces of from 2 to 40 or 50 square feet in area. This distinction between small and large exposed areas in the treatment of wind pressures is fundamental and should never be neglected.

This whole subject of wind pressures has not yet been brought into a completely definite or well-defined condition through lack of sufficient experimental observations, but in order to be at least reasonably safe civil engineers frequently, and perhaps usually, assume a wind pressure acting simultaneously on both bridge and train at 30 pounds per square foot of exposed surface and 50 pounds per square foot of the total exposed surface of a bridge structure which carries no moving load. This distinction arises chiefly from the fact that a wind pressure of 30 pounds per square foot on the side of many railroad trains, particularly light ones, will overturn them, and it would be useless to use a larger pressure for a loaded structure. There have been wind pressures in this country so great as to blow unloaded bridges off their piers; indeed in one case a locomotive was overturned which must have resisted a wind pressure on its exposed surface of not less than 90 pounds and possibly more than 100 pounds per square foot.

The consideration of wind pressure is of the greatest importance in connection with the high trusses of long spans, as well as in long suspension and cantilever bridges, and in the design of high viaducts, all of which structures receive lateral wind pressures of great magnitude.

Some engineers, instead of deducing the lateral wind loads from the area of the projected truss surfaces, specify a certain amount for each linear foot of span, as in ”The General Specifications for Steel Railroad Bridges and Viaducts” by Mr. Theodore Cooper it is prescribed that a lateral force of 150 pounds for each foot of span shall be taken along the upper chords of through-bridges and the lower chords of deck-bridges for all spans up to 300 feet in length; and that for the same spans a lateral force of 450 pounds for

each foot of span shall be taken for the lower chords of through-spans and the upper chords of deck-spans, 300 pounds of this to be treated as a moving load and as acting on a train of cars at a line 8■/■■ feet above the base of rail.

When the span exceeds 300 feet in length each of the above amounts of load per linear foot is to be increased by 10 pounds for each additional 30 feet of span.

Special wind-loadings and conditions under which they are to be used are also prescribed for viaducts.

These wind loads are resisted in the bridges on which they act by a truss formed between each two upper chords for the upper portion of the bridge, and between each two lower chords for the lower portion of the structure.

[Illustration: FIG. 26.]

=104. Upper and Lower Lateral Bracing.=—Fig. 26 shows what are called the upper and lower lateral bracing for such trusses as are shown in the preceding figures. The wind is supposed to act in the direction shown by the arrow. _DERA_ and _KLBC_ are the two portals at the ends of the structure, braced so as to resist the lateral wind pressures. It will be observed that the systems of bracing between the chords make an ordinary truss, but in a horizontal plane, except in the case of inclined chords like that of Fig. 24. In the latter case the lateral trusses are obviously not in horizontal planes, but they may be considered in computations precisely as if they were. These lateral trusses are then treated with their horizontal panel wind loads just as the vertical trusses are treated for their corresponding vertical loads, and the resulting stresses are employed in designing web and chord members precisely as in vertical trusses. The wind stresses in the chords, in some cases, are to be added to those due to vertical loading, and in some cases subtracted. In other words, the resultant stresses are recognized and the chord members are so designed as properly to resist them. At the present time it is the tendency in the best structural work to make all the web members of these lateral trusses of such section that they can resist both tension and compression, as this contributes to the general stiffness of the structure. On account of the great variability of the wind pressures and the liability of the blows of greatest intensity to vary suddenly, some engineers regard all the wind load on structure or train as a moving load and make their computations accordingly. It is an excellent practice and is probably at least as close an approximation to actual wind effects as the assumption of a uniform wind pressure on a structure.

Both the lateral and transverse wind bracing of railroad bridges have other essential duties to perform than the resistance of lateral wind pressures. Rapidly moving railroad trains produce a swaying effect on a bridge, in consequence of unavoidable unevenness of tracks, lack of balance of locomotive driving-wheels, and other similar influences. These must be resisted wholly by the lateral and transverse bracing, and these results constitute an important part of the duties of that bracing. These peculiar demands, in connection with the lateral stability of bridges, make it the more desirable that the lateral and transverse bracing should be as stiff as practicable.

=105. Bridge Plans and Shopwork.=—After the computations for a bridge design are completed in a civil engineer’s office they are placed in the drawing-room, where the most detailed and exact plans of every piece which enters the bridge are made. The numerical computations connected with this part of bridge construction are of a laborious nature and must be made with absolute accuracy, otherwise it would be quite impossible to put the bridge together in the field. The various quantities of bars, plates, angles, and other shapes required are then ordered from the rolling-mill by means of these plans or drawings. On receipt of the material at the shop the shopwork of manufacture is begun, and it involves a great variety of operations. The bridge-shop is filled with tools and engines of the heaviest description. Punches, lathes, planers, riveters, forges, boring and other machines of the largest dimensions are all brought to bear in the manufacture of the completed bridge.

=106. Erection of Bridges.=—When the shop operations are completed the bridge members are shipped to the site where the bridge is to be erected or put in place for final use. A timber staging, frequently of the heaviest timbers for large spans, called false works, is first erected in a temporary but very substantial manner. The top of this false work, or timber staging, is of such height that it will receive the steelwork of the bridge at exactly the right elevation. The bridge members are then brought onto the staging and each put in place and joined with pins and rivets. If the shopwork has not been done with mathematical accuracy, the bridge will not go together. On the accuracy of the shopwork, therefore, depends the possibility of properly fitting and joining the structure in its final position. The operations of the shop are so nicely disposed and so accurately performed that it is not an exaggeration to state that the serious misfit of a bridge member in American engineering practice at the present time is practically impossible. This leads to rapid erection so that the steelwork of a pin-connected railroad bridge 500 feet long can be put in place on the timber staging, or false works, and made safe in less than four days, although such a feat would have been considered impossible twenty years ago.

[Illustration: FIG. 27.]

=107. Statically Determinate Trusses.=—The bridge structures which have been treated require but the simplest analysis, based only on statical equations of equilibrium of forces acting in one plane, i.e., the plane of the truss. It is known from the science of mechanics that the number of those equations is at most but three for any system of forces or loads, viz., two equations of forces and one of moments. This may be simply illustrated by the system of forces _F■_, _F■_, etc., in Fig. 27. Let each force be resolved into its vertical and horizontal components _V_ and _H_. Also let _l■_, _l■_, etc. (not shown in the figure), be the normals or lever-arms dropped from any point _A_ on the lines of action of the forces _F■_, _F■_, etc., so that the moments of the forces about that point will be _F■l■_, _F■l■_, etc. The conditions of purely statical equilibrium are expressed by the three general equations

_H■ + H■_ + etc. = _F■_ cos _a■_ + _F■_ cos _a■_ + etc. = 0; (35) _V■ + V■_ + etc. = _F■_ sin _a■_ + _F■_ sin _a■_ + etc. = 0; (36) _Fl = F■l■ + F■l■_ + etc. = 0. (37)

If all the forces except three are known, obviously those three can be found by the three preceding equations; but if more than three are unknown, those three equations are not sufficient to find them. Other equations must be available or the unknown forces cannot be found. In modern methods of stress determinations those other needed equations express known elastic relations or values, such as deflections or the work performed in stressing the different members of structures under loads. A few fundamental equations of these methods will be given.

In Figs. 19, 20, and 21 let the truss be cut or divided by the imaginary sections _QS_. Each section cuts but three members, and as the loads and reactions are known, the stresses in the cut members will yield but three unknown forces, which may be found by the three equations of equilibrium (35), (36), (37). If more than three members are cut, however, as in the section _TV_ of Figs. 22 and 23, making more than three unknown equations to be found, other equations than the three of statical equilibrium must be available. Hence the general principle that _if it is possible to cut not more than three members by a section through the truss, it is statically determinate_, but _if it is not possible to cut less than four or more, the stresses are statically indeterminate_.

At each joint in the truss the stresses in the members meeting there constitute, with the external forces or loads acting at the same point, a system in equilibrium represented by the two equations (35) and (36). If there are _m_ such joints in the entire structure, there will be 2_m_ such equations by which the same number of unknown quantities may be found. Since equilibrium exists at every joint in the truss, the entire truss will be in equilibrium, and that is equivalent to the equilibrium of all the external forces acting on it. This latter condition is expressed by the three equations (35), (36), and (37), and they are essentially included in the number 2_m_. Hence there will remain but 2_m_ - 3 equations available for the determination of unknown stresses or external forces.

If, therefore, all the external forces (loads and reactions) are known, the 2_m_ - 3 equations of static equilibrium can be applied to the determination of stresses in the bars of the truss or other structure. It follows, therefore, that the greatest number of bars that a statically determinate truss can have is

_n_ = 2_m_ - 3. (38)

In Fig. 19 there are twelve joints and twenty-one members, omitting counter web members and the verticals _ab_ and _fl_, which are, statically speaking, either superfluous or not really bars of the truss. Hence

_m_ = 12 and 2_m_ - 3 = 21. (39)

Again, in Fig. 21 there are fifteen joints. Hence

_m_ = 15, 2_m_ - 3 = 27,

and there are twenty-seven bars or members of the truss. The number of joints and bars in actual, statically determinate trusses, therefore, confirm the results.

=108. Continuous Beams and Trusses—Theorem of Three Moments.=—These considerations find direct application to what are known as ”continuous beams,” i.e., beams (or trusses) which reach continuously over two or more spans, as shown in Fig. 28.

[Illustration: FIG. 28.]

The beam shown is continuous over three spans, but a beam or truss may be continuous over any number of spans. In general the ends of the beam or girder may be fixed or held at the ends _A_ and _D_, so that bending moments _M_ and _M■_ at the same points may have value. The bending moments at the other points of support are represented by _M■_, _M■_, etc. The points of support may or may not be at the same elevation, but they are usually assumed to be so in engineering practice. Finally, it is ordinarily assumed that the continuous structure is straight before being loaded, and that in that condition it simply touches the points of support. Whether the preceding assumptions are made or not, a perfectly general equation can be written expressing the relation between the bending moments over each set of three consecutive points of support, as _M_, _M■_, and _M■_, or _M■_, M■, and M■. Such an equation expresses what is called the "Theorem of Three Moments." It is not necessary to give the most general form of this theorem, as that which is ordinarily used embodies the simplifying assumptions already described. This simplified form of the "Theorem of Three Moments" applied to the case of Fig. 28 will yield the following two equations:

1 ■ _Ml■ + 2M■_(_l■ + l■_) + _M■l■_ + ---- ∑ _W_(_l■² - z²_)_z_ _l■_

1 ■ + ----- ∑ _W_(_l■² - z²__)z_ = 0. (40) _l■_

1 ■ _M■l■ + 2M■_(_l■ + l■_) + _M■l■_ + ------ ∑ _W_(_l■² - z²_) _l■_ 1 ■ + ---- ∑ _W_(_l■² - z²_)_z_ = 0. (41) _l■_

The figure over the sign of summation shows the span to which the summation belongs. If there is but one weight or load _W_ in each span, the sign of summation is to be omitted. In an ordinary bridge structure or beam the ends are simply supported and _M = M■ = 0_. In any case if the number of supports be _n_, there will be _n_ - 2 equations like the preceding.

If the end moments _M_ and _M■_ are not zero, they will be determinable by the local conditions in each instance. In any event, therefore, they will be known, and there will be but _n_ - 2 unknown moments to be found by the same number of equations. When the moments are known the reactions follow from simple formulæ.

=109. Application to Draw- or Swing-bridges.=—In general the reactions or supporting forces of the beams and trusses of ordinary civil-engineering practice are vertical, and all their points of application are known. Hence there are but two equations of equilibrium, equations (36) and (37), for external forces. These two equations for the external forces and the _n_ - 2 equations derived from the theorem of three moments are therefore always sufficient to determine the _n_ reactions. After the reactions are known all the stresses in the bars or members of the trusses can at once be found. The preceding equations and methods as described are constantly employed in the design and construction of swing- or drawbridges.

=110. Special Method for Deflection of Trusses.=—The method of finding the elastic deflections produced by the bending of solid beams has already been shown, but it is frequently necessary to determine the elastic deflections of bridge-trusses or other jointed or so-called articulate frames or structures. It is not practicable to use the same formulæ for the latter class of structures as for the former. The elastic deflection of a bridge- or roof-truss depends upon the stretching or compressions of its various members in consequence of the tensile or compressive forces to which they are subjected. Any method by which the deflection is found, therefore, must involve these elastic changes of length. There are a number of methods which give the desired expressions, but probably the simplest as well as the most elegant procedure is that which reaches the desired expression through the consideration of the work performed in the truss members in producing their elastic lengthenings and shortenings.

The general features of this method can readily be shown by reference to Fig. 29. It may be supposed that it is desired to find the deflection of any point, as _J_, of the lower chord produced both by the dead and live load which it carries. It is known from what has preceded that every member of the upper chord will be shortened and that every member of the lower chord will be lengthened; and also that generally the vertical web members will be shortened and the inclined web members lengthened. If there can be obtained an expression giving that part of the deflection of _J_ which is due to the change of length of any one member of the truss independently of the others, then that expression may be applied to every other member in the entire truss, and by taking the sum of all those effects the desired deflection will at once result. While this expression will be found for some one particular truss member, it will be of such a general form that it may be used for any truss member whatever; it will be written for the upper-chord member _BC_ in Fig. 29.

[Illustration: FIG. 29.]

The general problem is to determine the deflection of the point _J_ when the bridge carries both dead and moving load over the entire span, as shown in Fig. 29. The general plan of procedure is first to find the stresses due to this combined load in every member of the truss, so that the corresponding lengthening or shortening is at once shown. The effect of this lengthening and

shortening for any single member _BC_ in producing deflection at _J_ is then determined; the sum of all such effects for every member of the truss is next taken, and that sum is the deflection sought. In this case the vertical deflection will be found, because that is the deflection generally desired in connection with bridge structures, but precisely the same method and essentially the same formulæ are used to find the deflection in any direction whatever. The following notation will be employed:

Let _w_ = deflection in inches at any panel-point or joint of the truss;

" _P_ = any arbitrary load or weight supposed to be hung at the point where the deflection is desired and acting as if gradually applied. This may be taken as unity;

" _Z_ = stress produced in any member of truss by _P_;

" _S_ = stress produced in any member of truss by the combined dead and moving loads;

Let _l_ = length in inches of any member of the truss in which _Z_ or _S_ is found;

" _A_ = area of cross-section of same member in square inches;

" _E_ = coefficient of elasticity.

_S_ or _Z_ may be either tension or compression, and the formulæ will be so expressed that tension will be made positive and compression negative.

The change of length of the chord member _BC_ produced by a stress gradually increasing from zero to _S_ is

_S_ ----_l_. _AE_

If it be supposed that _BC_ is a spring of such stiffness that it will be compressed by the gradual application of _Z_ exactly as much as the shortening of the actual member by the stress _S_, the deflection of the point 4 with the weight _P_ hung from it, and due to that compression alone, will be precisely the same as that due to the actual shortening of _BC_ by the combined dead and moving loads.

It is known by one of the elementary principles of mechanics that, since _P_ acts along the direction of the vertical deflection _w_, the work performed by the weight _P_ over that deflection is equal to the work performed by _Z_ over the change of length _l_. Hence

_l l Sl_ --- _Pw_ = --- _Z_ ----, or 2 2 _AE_

_Z Sl_ _w_ = --- ----. (42) _P AE_

The quantity _Z÷P_ is the stress produced in the member by a unit load applied at the joint or point where the deflection is desired. Again, _S÷A_ is the stress per unit of area, i.e., intensity of stress, in the member considered by the actual dead and moving loads. For brevity let these be written

_Z S_ --- = _z_ and --- = _s_; _P A_

then

zsl _w_ = ------. (43) _E_

If the influence of every member of the truss is similarly expressed, the value of the total deflection produced by the dead and moving loads will be

zsl _w_ = ∑ ------. (44) _E_

The sign of summation ∑ indicates that the summation is to extend over all the web and chord members of the truss.

=111. Application of Method for Deflection to Triangular Frame.=—Before applying those equations to the case of Fig. 29 it is best to consider a simpler case, i.e., that of the triangular frame shown in Fig. 18. The reactions are

_l■ l■_ _R_ = --- _W_ and _R■_ = --- _W_. (45) _l l_

The stresses in the various members are:

_l■_ In _CB_, _S_ = ---- _W_ sec α. _l_

_l■_ ” _CA_, _S_ = ---- _W_ sec β. _l_

_l■ l■_ ” _AB_, _S_ = --- _W_ tan β = --- _W_ tan α. _l l_

Also: _CB = h_ sec α; area of section = _A■_. _CA = h_ sec β; ” ” ” = _A■_. _AB = l_; ” ” ” = _A■_.

In this instance it is simplest to take _P = W_. Equation (44) then gives

(_l■² h_ sec³ α _l■² h_ sec³ _β_ _w_ = (----- ---------- + ----- ---------- (_l² A■ l² A■_

_l■² l_ tan² _β_) _W_ + ---- ----------) ------. (46) _l² A■_) _E_

Let it be supposed that

_l_ = 25 feet = 300 inches; _h_ = 8 feet 4 inches = 100 inches; _l■_ = 16 feet 8 inches = 200 inches and _l■_ = 100 inches; tan β = 1; sec β = 1.414; sec α = 2.24; _W_ = 10,000 pounds.

If the bars are all supposed to be of yellow-pine timber, there may be taken

_E_ = 1,000,000 pounds; _A■_ = 10″ × 12″ = 120 square inches; _A■_ = 10″ × 10″ = 100 square inches; _A■_ = 10″ × 12″ = 120 square inches.

The insertion of these quantities in equation (46) gives the deflection

_w_ = .01042 + .01253 + .01111 = 0.034. (47)

Equation (47) is so written as to show the portion of the deflection due to each member of the frame.

In applying either equation (43) or equation (44) care must be taken to give each stress and its corresponding strain (lengthening or shortening) the proper sign. As the formulæ have been written and used, a tensile stress and its resulting stretch must each be written positive, while a compressive stress must be written negative. This holds true for both the stresses _Z_ and _S_ (or _z_ and _s_). The magnitude of the assumed load _P_ is a matter of indifference, since the stress _Z_ will always be proportional to it and the ratio _P ÷ Z_ will therefore be constant. _P_ is frequently taken as unity; or, as in the case just given, it may have any value that the conditions of the problem make most convenient.

=112. Application of Method for Deflection to Truss.=—In making application of the deflection formulæ to any steel railroad truss similar to that shown in Fig. 29, it will first be necessary to determine the stresses in all its members due to the dead and moving loads, since the deflection under the moving load is sought. These loads will be considered uniform, and that is sufficiently accurate for any railroad bridge. The moving train-load will be taken as covering the entire span, assumed, for a single-track railroad, 240 feet in length between centres of end pins. There are eight panels of 30 feet each, and the depth of truss at centre is 40 feet. Other truss dimensions are as shown in Fig. 29. The dead loads, or own weight, are taken at 400 pounds per linear foot of span for the rails and other pieces that constitute the track; at 400 pounds per linear foot for the steel floor-beams and stringers, and 1600 pounds per linear foot for the weight of trusses and bracing. The moving train-load will be taken at 4000 pounds per linear foot. This will make the panel-loads for each truss as follows:

Lower-chord dead load, 30 × 800 = 24,000 pounds per panel. Lower-chord moving load, 30 × 2000 = 60,000 ” ” ” ------ Total load on lower chord = 84,000 ” ” ” Upper-chord dead load, 30 × 400 = 12,000 ” ” ”

The structure is a “through” bridge, hence all moving loads rest on the lower chord.

[Illustration: FIG. 30.]

The stresses in the truss members due to the combined uniform dead and moving load are best found by the graphical method. One diagram only is needed to determine all the stresses, and it is shown in Fig. 30. This diagram is drawn accurately to scale, and the stresses measured from it are shown in the table on page 136.

The stresses in all the truss members due to the unit load hung at _J_ are readily found by the single diagram shown in Fig. 31, also carefully drawn to scale. These stresses measured from the diagram are given in the table as indicated by the column _z_; they are also represented in equation (44) by the letter _z_. The quantity _s_ in equation (44) is the intensity of the stress (pounds per square inch of cross-section of member) produced by the combined dead and moving loads in each member. As shown, these stresses are least in the web members near the centre of the span, and greatest in the chord members. The lengths in inches of the truss members are shown in the proper column of the table. It will be observed that all counter web members are omitted, as they are not needed for the uniform load. The coefficient of elasticity (_E_) is taken at 28,000,000 pounds. The quantities represented by the second member of equation (44) are computed from these data, and they appear in the last column of the table, the sum of which gives the desired deflection in inches. The elements of the table show how much of the deflection is due to the chords and to the web members, and they show that disregarding the latter would lead to a considerable error.

+-------+----------+---------+--------+-----+---------+ | | _S_ | _s_ | _z_ | _l_ | _w_ | +-------+----------+---------+--------+-----+---------+ | _L■_ | +373,300 | +12,000 | +.555 | 360 | +.08563 | | _L■_ | +373,300 | +12,000 | +.555 | 360 | +.08563 | | _L■_ | +480,000 | +12,000 | +.833 | 360 | +.1284 | | _L■_ | +540,000 | +12,000 | +1.125 | 360 | +.1736 | | _P■_ | -502,300 | -9,000 | -.748 | 472 | +.1132 | | _U■_ | -501,000 | -9,500 | -.870 | 376 | +.1108 | | _U■_ | -544,800 | -10,000 | -1.135 | 363 | +.1472 | | _U■_ | -576,000 | -10,000 | -1.50 | 360 | +.1928 | | _T■_ | +84,000 | +9,000 | 0 | 324 | -- | | _T■_ | +143,500 | +10,000 | +.3738| 472 | +.0629 | | _P■_ | -12,000 | -1,000 | -.250 | 432 | +.00386 | | _T■_ | +93,720 | +7,400 | +.456 | 562 | +.0677 | | _P■_ | +12,000 | +1,000 | -.35 | 480 | -.0060 | | _T■_ | +60,000 | +4,800 | +.625 | 600 | +.0643 | | _P■_ | -12,000 | -1,000 | 0 | 480 | -- | +-------+----------+---------+--------+-----+---------+

Deflection for ½ truss members = 1.2300 inches. Deflection at _J_ = 2 × 1.2300 = 2.4600 inches.

[Illustration: FIG. 31.]

As the deflection is usually desired in inches, the lengths of members must be taken in the same unit.

=113. Method of Least Work.=—The so-called theorem or principle of “Least Work” is closely related to the subject of elastic deflections just considered in its availability for furnishing equations of condition in addition to those of a purely statical character in cases where indetermination would result without them. This principle of least work is expressed in the simple statement that when any structure supports external loading the work performed in producing elastic deformation of all the members will be the least possible. Although this principle may not be susceptible of a complete and general demonstration, it may be shown to hold true in many cases if not all. The hypothesis is most reasonable and furnishes elegant solutions in many useful problems.

The application of this principle requires the determination of expressions for the work performed in the elastic lengthening and shortening of pieces subjected either to tension or compression, and for the work performed in the elastic bending of beams carrying loads at right angles to their axes. Both of these expressions can be very simply found.

Let it be supposed that a piece of material whose length is _L_ and the area of whose cross-section is _A_ is either stretched or compressed by the weight or load _S_ applied so as to increase gradually from zero to its full value. The elastic change of length will be _SL/AE_, _E_ being the coefficient of elasticity. The average force acting will be ½_S_, hence the work performed in producing the strain will be

1 _S²L_ --- -----. (48) 2 _AE_

It will generally be best, although not necessary, to take _L_ in inches. The expression (48) applies either to tension or compression precisely as it stands.

To obtain the expression for the work performed by the stresses in a beam bent by loads acting at right angles to its axis, a differential length (_dL_) of the beam is considered at any normal section in which the bending moment is _M_, the total length being _L_. Let _I_ be the moment of inertia of the normal section, _A_, about an axis passing through the centre of gravity of the latter, and let _k_ be the intensity of stress (usually the stress per square inch) at any point distant _d_ from the axis about which _I_ is taken. The elastic change produced in the indefinitely short length _dL_ when the intensity _k_ exists is (_k/E_)_dL_. If _dA_ is an indefinitely small portion of the normal section, the average force or stress, either of tension or compression, acting through the small elastic change of length just given, can be written by the aid of equation (5) as

_Md_ ½_k.dA_ = ----- ._dA._ (49) 2_I_

Hence the work performed in any normal section of the member, for which _M_ remains unchanged, will be, since ∫_k.dA.d_ = _M_,

∫ _M M²_ ∫ ------ _kd.dA.dL_ = ----- _dL._ (50) 2_IE_ 2_IE_

The work performed throughout the entire piece will then be

∫ _M²_ ∫ ------ _dL._ (51) 2_IE_

Each of the expressions (48) and (51) belongs to a single piece or member of the structure. The total work performed in all the pieces subjected either to direct stress or to bending, and which, according to the principle of least work, must be a minimum, is found by taking the summation of the two preceding expressions:

1 ■ _S²L_ 1 ■ ∫ _M²_ _e_ = ----■ ------ + ----- ■ ∫ ----- _dL_ = minimum. (52) 2_E_ _A_ 2_E_ _I_

In making an application of equation (52) it is to be remembered that _S_ is the direct stress of tension or compression in any member, and that _M_ is the general value of the bending moment in any bent member expressed in terms of the length _L_.

=114. Application of Method of Least Work to General Problem.=—The problem which generally presents itself in the use of equation (52) is the finding of an equation which expresses the condition that the work expended in producing elastic deformation shall be a minimum, some particular stress in the structure or some external load or force being the variable. If _t_ represent that variable, then the desired equation of condition will be found simply by placing the first differential coefficient of _e_ in equation (52) equal to zero:

_de_ 1 (■ _S dS_ ■ ∫ _M dM_) ----- = ----(■ --- --- _dL_ + ■ ∫ ---- --- _dL_) = 0. (53) _dt_ _E_(_A dt_ _I dt_)

The solution of equation (53) will give a value of _t_ which will make the work performed as expressed in equation (52) a minimum. This method is not a difficult one to employ in such cases as those of drawbridges and stiffened suspension bridges. In the latter case particularly it is of great practical value.

=115. Application of Method of Least Work to Trussed Beam.=—The method of least work may be illustrated by the application of the preceding equations to the simple truss shown in Fig. 32. The pieces _BC_ and _GD_ are supposed to be of yellow-pine timber, the former 10 inches by 14 inches (vertical) in section and the latter 8 inches by 10 inches, while each of the pieces _BD_ and _DC_ are two 1■-inch round steel bars. The coefficient of elasticity _E_ will be taken at 1,000,000 pounds for the timber and 28,000,000 for the steel. The length of _BC_ is 360 inches; _GD_ 96 inches; _BD_ = 96 × 2.13 = 204.5 inches.

tan α = 1.875 and sec α = 2.13.

The weight _W_ resting at _G_ is 20,000 pounds. A part of this weight is carried by _BC_ as a simple timber beam, while the remainder of the load will be carried on the triangular frame _BCD_ acting as a truss, the elastic deflection of the latter throwing a part of the load on _BC_ acting as a beam. According to the principle of least work the division of the load will be such as to make the work performed in straining the different members of the system a minimum.

That part of _W_ which rests on _BC_ as a simple beam may be represented by _W■_, while _W■_ represents the remaining portion carried by the triangular frame. As _G_ is at the centre of the span, the beam reaction at either _B_ or _C_ is ½_W■_. Hence the general value of the bending moment in either half of the beam at any distance _x_ from either _B_ or _C_ is

_M_ = ½_W■x._ Hence _M²dL_ = ¼_W■²x²dx_.

As there is but one member acting as a beam, whose moment of inertia _I_ is constant, the second term of the second member of equation (52) becomes, by the aid of the preceding equation,

1 1 ¹/■ 1 _W■²l³_ ----- ∫ _M²dL_ = ---- ∫ _¼W■²x²dx_ = ---- --------. (54) 2_EI_ ∫ _EI_ ∫■ _EI_ 96

[Illustration: FIG. 32.]

The numerical elements of the expression for the work done in the members of the triangular frame are:

Member. Stress. Length. Area of Section.

_BC_ ½_W■_ tan _α_ 360 inches = _I_ 140 square inches _DC_ ½_W■_ sec _α_ 204.5 ” 4.14 ” ” _DG_ _W■_ 96 ” 80 ” ”

10 × 14³ 27440 _I_ = -------- = ------- = 2286.7. 12 12

The substitution of those quantities in the first term of the second member of equation (52) will give

1 ■ _S²L_ 1 (_W■²_ tan² _α_.360 _W■²_.96) -----■ ----- = ---------- (---------- + ----------) 2_E A_ 2,000,000 (4 × 140 80)

2 _W■²_ sec² _α_ .204.5 + ---------- ---------- = .000,003,73 _W■²_. 56,000,000 4 × 4.14

The substitution of numerical quantities in equation (54) gives

1 _W■²l³_ ---- -------- = .000,213_W■²_. _EI_ 96

Or, since _W - W■ = W■_,

_e_ = .000,003,73_W■²_ + .000,213(_W - W■)²_. (55)

Hence

_de_ ---- = .000,007,46_W■_ - .000,426(_W - W■_) = 0. (56) _dW■_

The solution of this equation gives

_W■_ = .893_W_ = 19,660 pounds.

_W■_ = 340 ”

It is interesting to observe that the first term of the second member of equation (56) is the deflection of the point of application of _W■_ as a point in the frame, while the second term is the deflection of the point of application of _W■_ considered as a point of the beam. In other words, the condition resulting from the application of the principle of least work is equivalent to making the elastic deflections by _W■_ and _W■_ equal. Indeed equation (53) expresses the equivalence of deflections whenever the features of the problem are such as to involve concurrent deflections of two different parts of the structure.

=116. Removal of Indetermination by Methods of Least Work and Deflection.=—The indetermination existing in connection with the computations for such trusses as those shown in Fig. 22 and Fig. 23 can be removed by finding equations of condition by the aid of the method of least work or of deflections. It is evident that the component systems of bracing of which such trusses are composed must all deflect equally. Hence expressions may be found for the deflections of those component trusses, each under its own load. Since these deflections must be equal, equations of condition at once result. A sufficient number of such equations, taken with those required by statical equilibrium, can be found to solve completely the problem. Such methods, however, are laborious, and the ordinary assumption of each system carrying wholly the loads resting at its panel-points is sufficiently near for all ordinary purposes.

The method of least work can be very conveniently used for the solution of a great number of simple problems, like that which requires the determination of the four reactions under the four legs of a table, carrying a single weight or a number of weights, and many others of the same character.

CHAPTER X.

=117. The Arched Rib, of both Steel and Masonry.=—During the past ten or fifteen years the type of bridge structure called the arched rib has come into much use, and its merits insure for it a wider application in the future. It partakes somewhat of the nature of both truss and arch; or it may be considered a curved beam or girder. The ordinary beam or truss when placed in a horizontal position and loaded vertically yields only vertical reactions. Under the same conditions, however, the arched rib will produce both vertical and horizontal reactions, and the latter must either be resisted by abutments of sufficient mass, or by a tie-rod, usually horizontal, connecting the springing points of the rib.

The arched rib may be built solid, as was done in the early days of bridge-building in this country when engineers like Palmer, Burr, and Wernwag introduced timber arches in combination with their wooden trusses, or as a curved plate girder, one of the most prominent examples of which is the Washington Bridge across the Harlem River in the city of New York; or, again, as a braced frame or curved truss, like the 800 feet arched rib carrying the roadway traffic and trolley cars across the Niagara gorge, or like those used in such great railroad train-sheds as the Grand Central Station, New York, the Pennsylvania stations at Jersey City and Philadelphia, and the Philadelphia and Reading station in Philadelphia. Those are all admirable examples of steel arched ribs, and

they are built to sustain not only vertical loads but, in the case of station roofs, the normal or horizontal wind pressures.

Within a few years, less than ten, another type of arched rib has been brought into use and promises to be one of the most beautiful as well as the most substantial applications of this type of structure; that is, the arched rib of combined steel and concrete. Many examples of this type of structure already exist both in this country and in Europe, probably the most prominent of which in this country is that at Topeka, Kansas, across the Kansas River.

[Illustration: =FIG. 33.=]

[Illustration: =FIG. 34.=]

[Illustration: =FIG. 35.=]

The characteristic feature of this type of structure, so far as the stresses developed in it are concerned, is the thrust throughout its length, more or less nearly parallel to its axis, which is combined with the bending moments and shears similar to those found in ordinary bridge-trusses. This thrust is the arch characteristic and differentiates it in a measure from the ordinary bridge-truss, while the bending moments and shears to which it is subjected differentiate it, on the other hand, from the pure arch type or a series of blocks in which thrust only exists. The thrust, bending moments, and shears in arched ribs are all affected by certain principal features of design. Those features are either fixedness of the ends of the ribs or the presence of pin-joints at those ends or at the crown. Fig. 33 represents an arched rib with its ends _D_ and _F_ supposed to be rigidly fixed in masonry or by other effective means.

=118. Arched Rib with Ends Fixed.=—The railroad steel arched bridge at St. Louis, built by Captain Eads between 1868 and 1874, is a structure of this character. The three spans (two each 537 feet 3 inches and one 552 feet 6 inches in length from centre to centre of piers) consist of ribs the main members of which are composed of chrome steel. It was a structure of unprecedented span when it was built, and constituted one of the boldest pieces of engineering in its day. The chords of the ribs are tubes made of steel staves, and their ends are rigidly anchored to the masonry piers on which they rest. It is exceedingly difficult, indeed impossible, to fix rigidly the ends of such a structure, and observations in this particular instance have shown that the extremities of the ribs are not truly fixed, for the piers themselves yield a little, giving elastic motion under some conditions of loading.

=119. Arched Rib with Ends Jointed.=—The rib shown in Fig. 34 is different from the preceding in that pin-joints are supplied at each end, so that the rib may experience elastic distortion or strain by small rotations about the pins at _A_ and _B_. In the computations for such a design it is assumed that the ends of the rib may freely change their inclination at those points. As a matter of fact the friction is so great, even if no corrosion exists, as to prevent motion, but the presence of the pins makes no bending moment possible at the end joints, and the failure to move freely probably produces no serious effect upon the stresses in the ribs. The presence of these pin-joints simplifies the computations of stresses and renders them better defined, so that there is less doubt as to the actual condition of stress under a given load than in the type shown in Fig. 33 with ends fixed more or less stiffly. In Fig. 34, if the horizontal force _H_ exerted by the ends of the rib against the points of support is known, the remaining stresses in the structure can readily be computed; but neither in Fig. 34 nor in Fig. 33 are statical equations sufficient for the determination of stresses. Equations of condition, depending upon the elastic properties of the material, are required before solutions of the problems arising can be made.

=120. Arched Rib with Crown and Ends Jointed.=—The rib shown in Fig. 35 possesses one characteristic radically different from any found in the ribs of Figs. 33 and 34, in that it is three-jointed, one pin-joint being at the crown and one at each end. So far as the conditions of stress are concerned, this is the simplest rib of all. Since there is a pin-joint at the crown as well as at the ends, the bending moments must be zero at each of those three points whatever may be the condition of loading. The point of application of the force or thrust at the crown, therefore, is always known, as well as the points of application at the ends of the joints. As will presently be seen, this condition makes equations of statical equilibrium sufficient for the determination of all stresses in the rib, and no equations depending upon the elastic properties of the material are required. The stresses in this class of ribs, therefore, are more easily determined than in the other two, and they are better defined. These qualities have insured for it a somewhat more popular position than either of the other two classes. The ribs of the great train-sheds of the Pennsylvania and Reading railroads in Jersey City and in Philadelphia belong to this class, while those of the Grand Central Station at New York City belong to the class shown in Fig. 34, as does the arched rib across the Niagara gorge, to which reference has already been made.

=121. Relative Stiffness of Arch Ribs.=—Obviously the three-hinged ribs are less stiff than the two-hinged ribs or those with fixed ends. This is a matter of less consequence for station roofs than for structures carrying railroad loads. The joints of the two-hinged rib being at the ends of the structure, there is but little difference in stiffness between that class of ribs and those with ends fixed. Indeed the difference is so slight, and the uncertainty as to the degree of fixedness of the fixed ends of the rib is so great, that the latter type of rib possesses no real advantage over that with hinged ends.

=122. General Conditions of Analysis of Arched Ribs.=—In each of the three types of arched ribs shown in Figs. 33, 34, and 35 it is supposed that all external forces act in the vertical planes which contain the centre lines of the various members of the rib. There are, therefore, the three conditions of statical equilibrium expressed by the three equations (35), (36), and (37). In practically all cases, except those of arched ribs employed in roof construction, all the external loads are vertical. In such cases the equations of statical equilibrium of the entire structure may be reduced to two only, viz., equations (36) and (37). These features of the problems connected with the design of arched ribs will always make necessary, except in the case of the three-hinged rib (Fig. 35), equations of condition depending upon the elastic properties of the structure.

The rib represented by Fig. 33 is supposed to have its ends so fixed that the inclinations of the centre line at _F_ and _D_ will never change whatever may be the loading or the variation of temperature. This requires the application at each of those points of a couple whose moment varies in value, but which is always equal and opposite to the bending moment at the same point produced by the loads imposed on the rib. It is also to be observed that the loads resting upon the rib are not divided between the points of support _F_ and _D_ in accordance with the law of the lever, since the conditions of fixedness at the ends are equivalent to continuity. There are then to be found, as acting external to the rib, the two vertical reactions and the two moments at _F_ and _D_, as well as the horizontal thrust exerted at the ends of the structure, which is sometimes resisted by the tie-rod, making five unknown quantities. Inasmuch as all external loading is supposed to be vertical, equations (36) and (37) are the only statical equations available, and three others, depending upon the elastic properties of the structure, must be supplied in order to obtain the total of five equations of condition to determine the five unknown quantities. Inasmuch as the end inclinations remain unchanged, the total extension or compression of the material at any given constant distance from the axis of the rib taken between the two end sections _F_ and _D_ must be equal to zero. Similarly, whatever may be the amount or condition of loading, the vertical and horizontal deflections of either of the ends _F_ or _D_ in relation to the other must be zero, since no relative motion between these two points can take place. It is not necessary in these lectures to give the demonstration of the equations which express the three preceding elastic conditions, but if _M_ is the general value of the bending moment for any point of the rib, and if _x_ and _y_ are the horizontal and vertical coordinates of the centre line of the rib, taking the central point of the section at either _F_ or _D_ as an origin, those equations, taken in the order in which the elastic conditions have been named, will be the following, in which _n_ represents a short length of rib within which the bending moment _M_ is supposed to remain unchanged.

F F F ■ ■ ■ ■ _nM_ = 0; ■ _nMx_ = 0; ■ _nMy_ = 0. (57) D D D

The second and third of these equations express the condition that the vertical and horizontal deflections respectively of the two ends in reference to each other shall be zero. The conditions expressed by equation (57) are constantly used in engineering practice to determine the bending moments and stresses which exist in the arched rib with fixed ends. The graphical method is ordinarily used for that purpose, as its employment is a comparatively simple procedure for a rib whose curvature is any whatever.

If the rib has hinged joints at the ends, as in Fig. 34, obviously there can be no bending moment at either of those two points, and hence the two equations of condition which were required in connection with Fig. 33 to determine them will not be needed. There is, therefore, no restriction as to the angle of inclination of the centre line of the rib at those two points. Again, it is obvious that either end _A_ or _B_ may have vertical movement, i.e., deflection in reference to the other, without affecting the condition of stress in any member of the rib; but it is equally obvious that neither _A_ nor _B_ can be moved horizontally, i.e., deflected in reference to the other, without producing bending in the rib and developing stresses in the various members. The unknown quantities in this case are, therefore, only the horizontal thrust _H_ exerted at the two springing points _A_ and _B_, and the two vertical reactions, making a total of three unknown quantities, equations for two of which will be given by equations (36) and (37). The other equation required is the third expression in equation (57), expressing the condition that the horizontal deflection of either of the points _A_ or _B_ in respect to the other is zero, since the span _AB_ is supposed to remain unchanged. By the application of the graphical method to this case, as to the preceding, the employment of equations (36), (37), and (58) will afford an easy and quick determination of the three unknown quantities, whatever may be the curvature of the rib.

A ■ ■ _nMy_ = 0. (58) B

If the reactions and horizontal thrust _H_ are found, stresses in every member may readily be computed and the complete design made.

If the arch is three-hinged, as in Fig. 35, the condition that the bending moment must be zero at the crown _C_ under all conditions of loading gives a third statical equation independent of the elastic properties of the structure which, in connection with equations (36) and (37), give three equations of condition sufficient to determine the two vertical reactions and the horizontal thrust _H_. In this case, as has already been stated, no elastic equations of condition are required.

The determination of the end reactions, bending moments, and horizontal thrust _H_, in these various cases, is all that is necessary in order to compute with ease and immediately the stresses in every member of the rib. These computations are obviously the final numerical work required for the complete design of the structure. These procedures are always followed, and in precisely the manner indicated, in the design of arched ribs by civil engineers, whether the rib be articulated, i.e., with open bracing, or with a solid plate web, like those of the Washington Bridge across the Harlem River.

CHAPTER XI.

=123. Beams of Combined Steel and Concrete.=[2]—A reference has already been made to a class of beams and arches recently come into use and now quite widely employed, composed of steel and concrete, the former being completely surrounded by and imbedded in the latter. These composite beams are very extensively used in the floors of fire-proof buildings as well as for other purposes. Arches of combined concrete and steel were probably first built in Germany and but a comparatively few years ago. During the past ten years they have been largely introduced into this country, and many such structures have not only been designed but built. The most prominent design of arches of combined concrete and steel are those of the proposed memorial bridge across the Potomac River at Washington, for which a first prize was awarded as the result of a national competition in the early part of 1900. So far as the bending or flexure of these composite beams and arches is concerned, the theory is identically the same for both, the formulæ for each of which are given below. In order to express these formulæ the following notation will be needed:

[2] For a complete and detailed statement of this whole subject, including design work, reference should be made to the author's "Elasticity and Resistance of Materials."

_P_ is the thrust along the arch determined by the methods explained in the consideration of arched ribs.

_I_ is the distance of the line of the thrust _P_ from the axis of the arched rib.

_E■_ and _E■_ are coefficients of elasticity for the two materials.

_A■_ and _A■_ are areas of normal section of the two materials.

_I■_ and _I■_ are moments of inertia of _A■_ and _A■_ about the neutral axes of the composite beam or arch sections.

_k■_ and _k■_ are intensities of bending stress in the extreme fibres of the two materials.

_h■_ and _h■_ are total depths of the two materials.

_d■_ and _d■_ are distances from the neutral axes to farthest fibres of the two materials; distances to other extreme fibres would be (_h■-d■_) and (_h■-d■_).

_W■_ and _W■_ are loads, either distributed or concentrated, carried by the two portions.

_W = W■ + W■_ is total load on the beam or arch.

_q■ = W■/W_ and _q■ = W■/W_; ∴ _q■ + q■_ = 1; _e = E■/E■_.

The application of the theory of flexure to the case of a beam or arch of two different materials, steel and concrete in this case, will give the following results:

_M = Pl_; hence _M■ = q■Pl_ and _M■ = q■Pl_. (59)

_W■ E■I■_ _q■_ = --- = ---------- (60) _W E■I■ + E■I■_

_W■ E■I■_ _q■_ = --- = ---------- (61) _W E■I■ + E■I■_

_p Md_ _k■_ = ---------- + --------- (62) _A■ + eA■ I■ + eI■_

(_P Md_) _k■_ = _e_(---------- + ----------) (63) (_A■ + eA■ I■ + eI■_)

These formulæ exhibit some of the main features of the analysis which must be used in designing either beams or arches of combined steel and concrete. In the use of these equations care must be taken to give the proper sign to the bending moment _M_. They obviously apply to the combination of any two materials, although at the present time the only two used in such composite structures are steel and concrete. If the subscript 1 belongs to the concrete portion, and the subscript 2 to the steel portion, there may be taken _E■_ = 1,500,000 to 3,000,000 and _E■_ = 30,000,000. Hence _e_ = 20 to 10.

The purpose of introducing the steel into the concrete is to make available in the composite structure the high tensile resistance of that metal. A very small steel cross-section is sufficient to satisfactorily accomplish that purpose. The percentage of the total composite section represented by the steel will vary somewhat with the dimensions of the structure and the mode of using the material; it will usually range from 0.75 per cent to 1.5 per cent of the total section. The large mass of concrete in which the steel should be completely imbedded serves not only to afford a large portion of the compressive resistance required in both arches and beams, but also to preserve the steel effectively from corrosion. Many experiments have shown that it requires but a small per cent of steel section to give great tensile resistance to the composite mass.

CHAPTER XII.

=124. The Masonry Arch.=—The masonry arch is so old that its origin is lost in antiquity, but its complete theory has been developed with that of other bridge structures only within the latest period. It is only possible here to give some of the main features of that theory and a few of the fundamental ideas on which it is based. It is customary among engineers to regard the masonry arch as an assemblage of blocks finely cut to accurate dimensions, so that the assumption of either a uniform or uniformly varying pressure in the surface of contact between any two may be at least sufficiently near the truth for all practical purposes. Although care is taken to make joints between ring-stones or voussoirs completely cemented or filled with a rich cement mortar, it is usually the implicit assumption that such joints do not resist tension. As a matter of fact many arch joints are capable of resisting considerable tension, but, in consequence of settlement or shrinkage, cracks in them that may be almost or quite imperceptible frequently prevent complete continuity. It is, therefore, considered judicious to determine the stability of the ordinary masonry arch on the assumption that the joints do not resist tension.

In these observations it is not intended to convey the impression that no analysts treat the ordinary arch as a continuous elastic masonry mass, like the composite arches of steel and concrete. Although much may be said in favor of such treatment for all arches, it is believed that prolonged experience with arch structures makes it advisable to neglect any small capacity of resistance to tension which an ordinary cut-stone masonry joint may possess, in the interests of reasonable security.

The ring-stones or voussoirs of an arch are usually cut to form circular or elliptic curves, or to lines which do not differ sensibly from those curves. The arch-ring may make a complete semicircle, as in the old Roman arches, or a segment of a semicircle; or the stones may be arranged to make a pointed arch, like the Gothic; or, again, a complete semiellipse may be formed, or possibly a segment of that curve. When a complete semiellipse or complete semicircle is formed, the arches are said to be full-centred, and in those cases they spring from a horizontal joint at each end. On the other hand, segmental arches spring from inclined joints at each end called skew-backs.

=125. Old and New Theories of the Arch.=—In the older theories of the arch, considered as a series of blocks simply abutting against each other, the resultant loading on each block was assumed to be vertical. In the modern theories, on the other hand, the resultant loading on any block is taken precisely as it is, either vertical or inclined, as the case may be. Many arches are loaded with earth over their arch-rings. This earth loading produces a horizontal pressure against each of the stones, as well as a vertical loading due to its own weight. In such cases it is necessary to recognize this horizontal or lateral pressure of the earth, as it is called, as a part of the arch loading.

It is known from the theory of earth pressure that the amount of that pressure per square foot or any other square unit may vary between rather wide limits, the upper of which is called the abutting power of earth, and the latter the conjugate pressure due to its own weight only. If _w_ is the weight per cubic unit of earth and _x_ the depth considered, and if ϕ be the angle of repose of the earth, the abutting power per square unit will have the value:

$$1 + \sin \phi \quad p = wx \quad \text{---------}. \quad (64) \quad 1 - \sin \phi$$

while the horizontal or conjugate pressure due to the weight of earth only will be:

$$1 - \sin \phi \quad p\blacksquare = wx \quad \text{---------}. \quad (65) \quad 1 + \sin \phi$$

The use of these formulæ will be illustrated by actual arch computations.

[Illustration: FIG. 36.]

[Illustration: FIG. 37.]

Fig. 36 is supposed to show a set of ring-stones for an arch of any curvature whatever. The joints _LM_ and _ON_ represent the skew-backs or springing joints, while _R_ and _R■_ represent the supporting forces or reactions with centres of action at _a■_ and _a■_. The ring is divided into blocks or pieces by the joints at _a_, _b_, _c_, _d_, and _e_, the resultant loading or force on each block being given by the lines with arrow-heads and numbered 1, 2, 3, 4, 5, 6, and 7. Fig. 37 represents a force polygon constructed in the ordinary manner by laying off carefully to scale the two reactions _R_ and _R■_, together with the loads or forces numbered 1 to 7, inclusive. By constructing the so-called polygonal frame in the ring-stones of Fig. 36 in the usual manner with its lines or sides parallel to the radiating lines in Fig. 37, as shown by the broken lines, the points _a_, _b_, _c_, etc., are found where the resultant forces cut each joint. The line drawn through those points thus determined is called the line of resistance of the arch. Obviously, if that line of resistance be determined, the complete stability or instability of the arch, as the case may be, will be established. Furthermore, the complete determination of the force polygon in Fig. 37, and the corresponding polygonal frame drawn in the arch-ring, constitute all the computations involved in the design of an arch.

The thrust _T■_ at the crown, shown both in Fig. 36 and Fig. 37, is frequently horizontal, although not necessarily so; its value is shown by Fig. 37. In the older arch theories a principle was enunciated called the “principle of least resistance.” The thrust _T■_ is a fundamental and so-called passive force. That is, its magnitude depends not only upon its position, but also largely upon the magnitude of the active forces which represent the loading on the arch-ring. Under the principle of least resistance it was laid down as a fundamental proposition, in making arch computations, that this passive force _T■_ must be the least possible consistent with the stability of the structure. While this provisional proposition answered its purpose well enough, there are other clearer methods of procedure which are thoroughly rational and involve the employment of no extraneous considerations other than those attached to the determination of statical equilibrium.

A scrutiny of the conditions existing in Fig. 36 will show that if the external forces or loadings on the individual blocks of the ring are given, four quantities are to be determined, viz., the two reactions _R_ and _R■_ and their lines of action. Inasmuch as no elastic features of the structure are to be considered, there are available for the determination of these four quantities the three equations of equilibrium, equations (35), (36), and (37), which are not sufficient for the purpose. If one line of action, such as that of _R_, be located by assuming its point of application _a■_, the three equations just named will be sufficient for the determination of the remaining three equations; and that is precisely the method employed. It is tentative, but perfectly practicable. If, instead of assuming one of the points of application of the reactions, we assume both of those points and construct a trial polygonal frame, it will be necessary to use but two of the three equations of statical equilibrium. For that purpose there are employed equations (35) and (36), but in a graphical manner, which will presently be illustrated.

=126. Stress Conditions in the Arch-ring.=—Before proceeding to the construction of an actual line of resistance, a little consideration must be given to the stress conditions in the arch-ring. As the joints are considered capable of resisting no tension, the dimensions of the arch-ring must be finally so proportioned that pressure only will exist in each and every joint. If each centre of pressure, as _a_, _b_, etc., in Fig. 36, is found in the middle third of the joint, it is known from a very simple demonstration in mechanics that no tension will ever exist in that joint, although the pressure may be zero at one extremity and a maximum at the other. This is the condition usually imposed in designing an arch-ring to carry given dead or live loads. It is usually specified that "the line of resistance of the ring must lie in the middle third." It must be borne in mind, however, that the stability of the ring is perfectly consistent with the location of the line of resistance outside of the limits of the middle third, provided it is not so far outside as to induce crushing of the ring-stones. Whenever that crushing begins the arch is in serious danger and complete failure is likely to result.

=127. Applications to an Actual Arch.=—These principles will be applied to the arch-ring shown in Fig. 38, in which the clear span _TU_ is 90 feet. The radius _CO_ of the soffit (as the under surface of the arch is called) is 50 feet, the ring being circular and segmental. The uniform thickness of the ring shown at the various joints is assumed at 4 feet as a trial value. The loading above the ring to the level of the line _E■O_ is assumed to be dry earth weighing, when well rammed in place, 100 pounds per cubic foot. The depth of this earth filling at the crown _n_ of the arch is taken at 4 feet. The ring-stones are assumed to be of granite or best quality of limestone, weighing 160 pounds per cubic foot. The thickness or width of arch-ring of one foot is assumed, as each foot in width is like every other foot, and the loads are taken for that width of ring. The rectangle _EJJ■E■_ is supposed to represent a moving load covering one half of the span and averaging 500 pounds per linear foot; in other words, averaging 500 pounds per square foot of upper surface projected in the line _E■O_. The total length of the arch-ring, measured on the soffit, is about 113 feet, and it is divided into ten equal portions for the purpose of convenient computation. The radial joints so located are as shown at _de_, _fg_, _hk_. From the points where these joints cut the extrados (as the upper surface of the arch-ring is called) vertical broken lines are erected, as shown in Fig. 38.

[Illustration: FIG. 38.]

The horizontal line drawn to the left from _f_ gives the vertical projection of that part of the extrados between _d_ and _f_, and the horizontal earth pressure on _df_ will be precisely the same in amount as that on the vertical projection of _df_, as just found. In the same manner the horizontal earth pressure on that part of the extrados between any two adjacent joints may be found. The mid-depths of these vertical projections below the line _E′O_ are to be carefully measured by scale and then used for the values of _x_ in equations (64) and (65), which now become equations (66) and (67), as the angle of repose ϕ is taken to correspond to a slope of earth surface of 1 vertical on 1½ horizontal.

_p = 3.51wx._ (66)

_p■ = 0.285wx._ (67)

The horizontal earth pressures thus found are as follows:

_h■_ = { 101,500 pounds; _h■_ = { 30,625 pounds; { 8,700 " { 2,625 "

_h■_ = { 59,500 " _h■_ = { 9,800 " { 5,100 " { 840 "

These quantities _h■_, etc., are found by multiplying the two intensities _p_ and _p′_ by the vertical projections of the surface on which they act. The larger values are found by equation (66) and represent the abutting power of the earth, while the smaller values are found by equation (67), and represent the horizontal or conjugate pressure of the earth due to its own weight only. The actual

horizontal earth pressure against the arch-ring may lie anywhere between these limits.

The weights of the moving load, earth, and ring-stones between each pair of vertical lines and radial joints shown in Fig. 38 are next to be determined, and they are as follows:

_W■_ = 27,300 pounds; _W■_ = 12,300 pounds; _W■_ = 27,900 ” _W■_ = 15,550 ” _W■_ = 24,500 ” _W■_ = 19,500 ” _W■_ = 21,300 ” _W■_ = 19,400 ” _W■_ = 18,300 ” _W■■_ = 24,300 ”

The centres of gravity of these various vertical forces are shown in Fig. 38 at the points _W■_, _W■_, etc. The triangles of forces shown in that figure and composed, each one, of a vertical and horizontal force as described, are laid down in actual position on the arch-ring, as shown. All data are thus secured for completing the force polygon and polygonal frame or line of resistance. It will be assumed that the reactions _R_ and _R′_ cut the springing joints at _c_ and _a_, respectively, one third of the width of the joint from the soffit, and it will further be assumed that _b_, the mid-point of the joint at the crown, is also in the line of resistance. The assumption of the location of these three points is made for the reason, as is well known, that with a given system of forces a polygonal frame may be found which will pass through any three points in the ring.

[Illustration: FIG. 39.]

The force polygon _B_, 1, 2, 3, ..., 10, _A_, Fig. 39, is then drawn with the loadings on each ring segment found as already explained. The horizontal forces are taken as represented by the smaller values of _h■_, _h■_, _h■_, _h■_. Other force polygons with larger values of these horizontal forces were tried and not found satisfactory. Having constructed the force polygon and assumed the trial pole _P■_, the radial lines are drawn from it as shown in Fig. 39. The polygonal frame shown in broken lines in Fig. 38 results from this trial pole. The frame practically passes through _b_ and _c_, but leaves the ring, passing outside of it, above the joint _VU_. The point _q_ in this frame is vertically above _a_. The “three-point” method of finding the frame that will pass through _a_, _b_, and _c_ was then employed. The line _A6_, Fig. 39, was drawn; then _P′D_ was drawn parallel to _qb_, Fig. 38 (not shown); after which _PD_ was drawn parallel to _ab_, until it intercepted the horizontal line _PQ_, the line _P■Q_ having previously been drawn parallel to _qc_ (not shown). The final pole _P_ was thus found. The polygonal frame shown in full lines in the arch-ring was then drawn with sides parallel to the lines radiating from _P_, all in accordance with the usual methods for such graphic analysis. That polygonal frame lies within the middle third of the arch-ring, although at three points it touches the limit of the middle third. The arch, therefore, is stable.

This construction shows that, with the actual loading of the ring, a line of resistance can be found lying within the middle third; its stability under the conditions assumed is, therefore, demonstrated. It does not follow that the line of resistance as determined must necessarily exist, since there may be others located still more favorably for stability. This indetermination results from the fact already observed that the equations of statical equilibrium are not sufficient in number to determine the four unknown quantities (the two horizontal and the two vertical reactions); but the process of demonstrating the stability of the arch-ring is simple and sufficient for all ordinary purposes. The line of resistance found, if not the true one, is so near to it that no sensible waste of material is involved in employing it. This indetermination has prompted some engineers and other analysts to consider all arch-rings as elastic, thus obtaining other equations of condition. While such a procedure may be permissible, it is scarcely necessary, and perhaps not advisable, in view of the fact that many joints of cut-stone arches become slightly open by very small cracks, resulting possibly from unequal settlement, quite harmless in themselves, having practically no effect upon the stability of the structure.

=128. Intensities of Pressure in the Arch-ring.=—It still remains to ascertain whether the actual pressures of masonry in the arch-ring are too high or not. The greatest single force shown in the force polygon in Fig. 39 is the reaction _R_, having a value by scale of 122,000 pounds, under the left end of the arch, and it is supposed to act at the limit of the middle third of the joint. Hence the average pressure on that joint will be

122,000 × 2 ---------- = 61,000 pounds per square foot. 4

This value may be taken as satisfactory for granite or the best quality of limestone.

Again, it is necessary in bridges, as in some other structures, to determine whether there is any liability of stones to slip on each other. In order that motion shall take place the resultant forces acting on the surface of a stone joint must have an inclination to that surface less than a value which is not well determined and which depends upon the condition of the surface of the stone; it certainly must be less than 70°. The inclination of every resultant force in Fig. 38 to the surface on which it acts is considerably greater than that value and, hence, the stability of friction is certainly secured.

=129. Permissible Working Pressures.=—The working values of pressures permissible on cut-stone and brick or other masonry must be inferred from the results of the actual tests of such classes of masonry in connection with the results of experience with structures in which the actual pressures existing are known. It is safe to state that with such classes of material as are used in the best grade of engineering structures these pressures will generally be found not to exceed the following limits:

Concrete, 20,000 to 40,000 pounds per square foot.

Cement rubble, same values.

Hard-burned brick, cement mortar joints, 30,000 to 50,000 pounds per square foot.

Limestone ashlar, 40,000 to 60,000 pounds per square foot.

Granite ashlar, 50,000 to 70,000 pounds per square foot.

The masonry arch is at the same time the most graceful and the most substantial and durable of all bridge structures, and it is deservedly coming to be more and more used in modern bridge practice. One of the greatest railroad corporations in the United States has, for a number of years, been substituting, wherever practicable, masonry arches for the iron and steel structures replaced. The high degree of excellence already developed in this country in the manufacture of the best grades of hydraulic cement at reasonable prices, and the abundance of cut stone, has brought this type of structure within the limits of a sound economy where cost but a few years ago would have excluded it. It is obviously limited in use to spans that are not very great but yet considerably longer than any hitherto constructed.

[Illustration]

[Illustration: FIG. 40.—Elevation of Luxemburg Bridge and Sections of Main Span.]

=130. Largest Arch Spans.=—The longest arch span yet built has been but recently completed in Germany at the city of Luxemburg. This bridge has a span of 275.5 feet and a rise of 101.8 feet. It is rather peculiarly built in two parallel parts separated 19.5 feet in the clear, the space between being spanned by slabs or beams of combined concrete and steel. The arch-ring is 4.75 feet thick at the crown and 7.18 feet thick at a point 53.14 feet vertically below the crown where it joins the spandrel masonry. The roadway is about 52.5 feet wide and 144.5 feet above the water in the Petrusse River, which it spans.

[Illustration: Cabin John Bridge, near Washington, D. C.]

The longest arch in this country is known as the Cabin John Bridge of 220 feet span and 57.5 feet rise. It is a segmental arch and is located a short distance from the city of Washington, carrying the aqueduct for the water-supply of that city. These lengths of span may be exceeded in good ordinary masonry construction, but the high degree of strength and comparative lightness which characterize the combination of steel and concrete will enable bridges to be built in considerably greater spans than any yet contemplated in cut-stone masonry.

CHAPTER XIII.

=131. Cantilever and Stiffened Suspension Bridges.=—There are two other types of bridges of later development which have, in recent years, become prominent by remarkable examples of both completed structure and design; they are known as the cantilever and stiffened suspension bridges. Both are adapted to long spans, although the latter may be applied to much longer spans than the former. A cantilever structure, with a main span of 1800 feet between centres of piers, is now in process of construction across the St. Lawrence River at Quebec, while the well-known Forth Bridge across the Firth of Forth in Scotland has a main span of 1710 feet. The longest stiffened suspension bridge yet constructed is the New York and Brooklyn Bridge, with a river span of about 1595.5 feet between centres of towers, but the stiffened suspension system has been shown by actual design to be applicable to spans of more than 3200 feet, with material now commercially produced.

[Illustration: FIG. 41.]

[Illustration: FIG. 42.—Monongahela Bridge—Pittsburgh, Carnegie & Western Railroad (Wabash), at Pittsburgh.]

=132. Cantilever Bridges.=—Figs. 41 and 42 exhibit in skeleton outline two prominent cantilever designs for structures in this country. That shown in Fig. 41 was intended for a bridge across the Hudson River between Sixtieth and Seventieth streets, New

York City. The main central opening has a span of 1800 feet, and a length of 2000 feet between centres of towers. Fig. 42 shows the Monongahela River cantilever bridge,[3] now being built at Pittsburgh, Penn. Both figures exhibit the prominent features of the cantilever system. The main parts are the towers, at each end of the centre span, which are 534.5 feet high in the North River Bridge and 135 feet high in the Monongahela River structure, and the central main or river span with its simple non-continuous truss hung from the ends of the cantilever brackets or arms which flank it on both sides. These cantilever arms are simply projecting trusses continuous with the shore- or anchor-arms. They rest on the piers at either end of the main span, as a lever rests on its fulcrum. This arrangement requires the shore extremities or the anchor-arms to be anchored down by a heavy weight formed by the masonry piers at those points. Recapitulating and starting from the two shore ends of the structure, there are the anchor-spans, continuous at the towers, with the cantilever arms projecting outward toward the centre of the main opening and supporting at their ends the suspended truss, which is a simple, non-continuous one. It is thus evident that the cantilever bridge is a structure composed of continuous trusses with points of contraflexure permanently fixed at the ends of the suspended span. The greatest bending moments are at the towers, and the great depth at that point is given for the purpose of affording adequate resistance to those moments by the members of the structure. The following statement shows some elements of the more prominent cantilever bridges of this country and of the Forth Bridge:

[3] This bridge was designed by and is being constructed under the direction of Messrs. Boller and Hodge, Consulting Engineers, New York City.

Length of Cantilever Name. Opening, Centre to Total Length. Centre of Towers.

Pittsburgh 812 feet. 1504 feet. Red Rock (Colo.) 660 ” 990 ” Memphis (Tenn.) 790.48 ” 2378.2 ” Forth 1710 ” 5330 ”

The arrangement of web members of cantilever structures is designed to be such as will transfer the loads from the points of application to the points of support in the shortest and most direct paths. Both Figs. 41 and 42 show these general results accomplished by an advantageous arrangement of web members.

It is interesting to note that the first cantilever bridge designed and built in this country was constructed in 1871. This structure was designed and erected by the late C. Shaler Smith, a prominent civil engineer of his day.

=133. Stiffened Suspension Bridges.=—The stiffened suspension bridge is a structure radically different in its main features and its mode of transferring load to points of support from any heretofore considered, except arched ribs. When a load is supported by a beam or truss, the stresses, either in the web members of the truss or in the solid web of the beams, travel up and down those members in zigzag directions with a relatively large amount of metal required for that kind of transference. That metal is represented by the weight of the web members of the truss and of the solid web of the beam. Again, there are two sets of truss members—the chords or flanges, one of which sustains tension and the other an equal amount of compression. The greater part of this metal must be so placed and used that the working intensities of stress are comparatively small. This is particularly the case in compression members of both chords and webs which constitute the greater portion of the weight of the truss. All compression members are known as long columns which sustain not only direct compression but bending, and the amount of stress or load which they carry per square inch is relatively small, decreasing as the length increases. For all these reasons the amount of metal required for both beams and trusses is comparatively large. In suspension bridges, however, the conditions requiring the employment of a relatively large amount of metal with relatively small unit stresses are absent. The main members of a suspension bridge are the cables and the stiffening trusses, the latter being light in reference to the length of span. The cables are subjected to tension only, which is the most economical of all methods of using metal. A member in tension tends to straighten itself, so that it is never subjected to bending by the load which it carries. The opposite condition exists with compression members. Again, grades of steel possessing the highest ultimate resistance may be used in the manufacture of cables. It is well known that wire is the strongest form in which either wrought-iron or steel can be manufactured. While the ultimate tensile resistance of ordinary structural steel will seldom rise above 70,000 pounds per square inch, steel wire, suitable to be used in suspension-bridge cables, may be depended upon, at the present time, to give an ultimate resistance of at least 180,000 pounds per square inch. The elastic limit of ordinary structural steel is but little above half its ultimate resistance, while the elastic limit of the steel used in suspension-bridge cables is probably not less than three fourths of its ultimate resistance. It is seen, therefore, that the high resistance of steel wire makes the steel cable of the suspension bridge a remarkably economical application of metal to structural purposes.

The latest example of stiffened suspension-bridge is the new East River Bridge reaching across the East River from Broadway in Brooklyn to Delancey Street, New York City, now being built, with a main span of 1600 feet between centres of towers. The entire

length of the metal structure is 7200 feet, and the elevation of the centres of cable at the tops of the towers is 333 feet above mean high water.

Fig. 43 shows a view of this bridge. Its three principal divisions are the cables, the stiffening trusses, and the towers. The latter afford suitable points of support for the cables, which not only extend over the river span, but are carried back to points on the land where they are securely attached to a heavy mass of anchorage masonry. These anchorages must be sufficiently heavy to prevent any load which may come upon the bridge from moving them by the pull of the cables. It is usual to make these masses so great that they are capable of resisting from two to two and a half times the pull of the cables.

[Illustration: FIG. 43.—New East River Bridge.]

=134. The Stiffening Truss.=—The function of the stiffening trusses is peculiar and imperatively essential to the proper action of the whole system. If they are absent and a weight should be placed upon the cable at any point, a deep sag at that point would result. If a moving load should attempt to pass along a roadway supported by a cable only, the latter would be greatly distorted, and it would be impossible to use such a structure for ordinary traffic. Some means must then be employed by which the cable shall maintain essentially the same shape and position, whatever may be the amount of loading. It can be readily shown that if any perfectly flexible suspension-bridge cable carries a load of uniform intensity over the span from one tower to the other, the curve of the cable will be a parabola, with its vertex at the lowest point. Furthermore, it can also be shown that if any portion of the span be subjected to a uniform load, the corresponding portion of the cable will also assume a parabolic curve. It is assumed in all ordinary suspension-bridge design that the total weight of the structure, including the cables and the suspension-rods which connect the stiffening trusses to the cable, is uniformly distributed over the span, and that assumption is essentially correct. So far as the weight of the structure is concerned, therefore, the curve of the cable will always be parabolic. It only remains, therefore, to devise such stiffening trusses as will cause any moving load passing on or over the bridge to be carried uniformly to the cables throughout the entire span. This condition means that if any moving load whatever covers any portion of the span, the corresponding pull of the suspension-rods on the cables must be uniform from one tower to the other, and that result can be practically accomplished by the proper design of stiffening trusses; it is the complete function of those trusses to perform just that duty.

=135. Location and Arrangement of Stiffening Trusses.=—It has been, and is at the present time to a considerable extent, an open question as to the best location and arrangement of the stiffening trusses. The more common method in structures built is that illustrated by the New York and Brooklyn and the new East River bridges. Those stiffening trusses are uniform in depth, extending from one tower to the other, or into the land spans, and connected with the cables by suspension-rods running from the latter down to the lower chords of the trusses. It is obvious that the floor along which the moving load is carried must have considerable transverse stiffness, and hence it may appear advisable to place the stiffening trusses so that the floor may be carried by them. On the other hand, some civil engineers maintain that it is a better distribution of stiffening metal to place it where the cables themselves may form members of the stiffening trusses, with a view to greater economy of material.

Figs. 44, 45, and 46 illustrate some of the principal proposed methods of constructing stiffening trusses in direct connection with the cables. The structure shown in Fig. 44 illustrates the skeleton design of the Point Bridge at Pittsburgh. The curved member is a parabolic cable composed of eye-bars. This parabolic cable carries the entire weight of the structure and moving load when uniformly distributed. If a single weight rests at the centre, the two straight members of the upper chord may be assumed to carry it. If a single weight rests at any other point of the span, it will be distributed by the bracing between the straight and curved members of the stiffening truss. Obviously the most unbalanced loading will occur when one half of the span is covered with moving load. In that case the bowstring stiffening truss in either half of Fig. 44 will make the required distribution and prevent the parabolic tension member from changing its form.

[Illustration: FIG. 44.]

[Illustration: FIG. 45.]

[Illustration: FIG. 46.]

The type of bracing shown in Fig. 45 possesses some advantages of a peculiar nature. Each curved lower chord of the stiffening truss corresponds to the position of the perfectly flexible cable with the moving load covering that half of the span which belongs to the greatest sag of the cable. The two parabolic cables thus cross each other in a symmetrical manner at the centre of the span. If the moving load covers the entire span, the line of resistance or centre line of imaginary cable will be the parabola, shown by the

broken line midway along each crescent stiffening truss. The diagonal bracing placed between the cables is so distributed and applied as to maintain the positions of cables under all conditions of loading.

The mode of constructing the stiffening truss between two cables, shown in Fig. 46, is that adopted by Mr. G. Lindenthal in his design for a proposed stiffened suspension bridge across the Hudson River with a span of about 3000 feet. The two cables are parabolic in curvature and may be either concentric or parallel. This system of stiffening bracing possesses some advantages of uniformity and is well placed to secure efficient results. The same system has been used in suspension bridges of short span by Mr. Lindenthal at both St. Louis and Pittsburgh. The stiffening bracing produces practically a continuous stiffening truss from one tower to the other, whereas the systems shown in Figs. 44 and 45 involve practically a joint at the centre of the span.

In all these three types of vertical stiffness the floor is designed to meet only the exigencies of local loading, being connected with the stiffening truss above by suspension bars or rods, preferably of stiff section.

When stiffening trusses are placed along the line of the floor, as in the case of the two East River bridges, to which reference has already been made, those trusses need not necessarily be of uniform depth, and they may be continuous from tower to tower or jointed at the centre, like those of the New York and Brooklyn suspension bridge. This centre joint detracts a little from the stiffness of the structure, but in a proper design this is not serious.

=136. Division of Load between Cables and Stiffening Truss.=—In a case where continuous stiffening trusses are employed it is obvious that they may carry some portion of the moving load as ordinary trusses. The portion so carried will be that which is required to make the deflection of the stiffening truss equal to that of the cable added to the stretch of the suspension-rods. In the old theory of the stiffening truss constructed along the floor of the bridge this effect was ignored, and the computations for the stresses in those trusses were made by the aid of equations of statical equilibrium only. That assumption, that the cable carried the entire load, was necessary to remove the ambiguity which would otherwise exist. In modern suspension-bridge design those trusses may be assumed continuous from tower to tower with their ends anchored at the towers, or they may be designed to be carried continuously through portions of the land spans and held at their extremities by struts reaching down to anchorages, so that those ends may never rise nor fall, but move horizontally if required. If there are no pin-joints in the trusses at the centre and ends of the main span, equations of statical equilibrium are not sufficient to enable the reactions under the trusses and the horizontal component of cable tension to be found.

One of the best methods of procedure for such cases is that of least work, in which the horizontal component of cable tension is so found that the total work performed in the elastic deflection of the stiffening trusses, suspension-rods, cables, and towers is a minimum. After having found this horizontal component of the cable tension and the reactions under the stiffening trusses, the stresses in all the members of the entire structure can be at once determined. It is obvious that the stiffening truss and the cables must deflect together. It is equally evident that the deeper the stiffening trusses are the more load will be required to deflect them to any given amount, and hence that the deeper they are the more load they will carry independently of the cable. It is desirable to throw as much of the duty of carrying loads upon the cables as possible. It therefore follows that the stiffening trusses should be made as shallow as the proper discharge of their stiffening duties will permit.

=137. Stresses in Cables and Moments and Shears in Trusses.=—The necessary limits of this discussion will not permit even the simplest analyses to be given. It is evident, however, that the greatest cable stresses will exist at the tops of the towers, and that if the horizontal component of cable tension be found by any proper method, the stress at any other point will be equal to that horizontal component multiplied by the secant of cable inclination to a horizontal line, it being supposed that the suspenders are found in a vertical plane.

If the stiffening trusses are jointed at the centre of the main span, as well as at the ends, the simple equations of statical equilibrium are sufficient in number to make all computations, for the reason that the centre pin-joint gives the additional condition that, whatever may be the amount or distribution of loading, the centre moment must be zero. If _l_ is the length of main or centre span and _p_ the moving load per linear foot of span, and if the stiffening trusses run from tower to tower, the following equations will give their greatest moments and shears both by the old and new theory of the stiffening truss.

_p_ = load per lin. ft., _l_ = length of span in ft., Old theory. New theory.

Max. moment _M_ = 0.01856_pl_² _M_ = 0.01652_pl_²}no centre Max. shear _S_ = ■_pl_ _S_ = ■_pl_ } hinge. With centre hinge _M_ = 0.01883_pl_² and _S_ = ■_pl_

The details of the theory of stiffening trusses for suspension bridges have been well developed during the past few years and are fully exhibited in modern engineering literature. The long spans requiring stiffened suspension bridges are usually found over navigable streams, and hence those bridges must be placed at comparatively high elevations. This is illustrated by the clear height of 135 feet required under the East River suspension-bridge structures already completed and in progress. Furthermore, the heights of towers above the lowest points of the cables usually run from one eighth to one twelfth of the span. These features expose the entire structure to comparatively high wind pressures, which must be carefully provided against. This is done by the requisite lateral bracing between the stiffening trusses and by what is called the cradling of the cables. The latter expression simply means that the cables as they are built are swung out of a vertical plane and toward the axis of the structure, being held in that position by suitable details. The cables on opposite sides of the bridge are thus moved in toward each other so as to produce increased stability against lateral movement. Occasionally horizontal cables are stretched between the towers in parabolic curves in order to resist horizontal pressures, just as the main cables carry vertical loads. This matter of stability against lateral wind pressures requires and receives the same degree of careful consideration in design as that accorded to the effects of vertical loading. The same general observation applies also to the design of the towers.

=138. Thermal Stresses and Moments in Stiffened Suspension Bridges.=—All material used in engineering structures expands and contracts with rising and falling temperatures to such an extent that the resulting motions must be provided for in structures of considerable magnitude. In ordinary truss-bridges one end is supported upon rollers, so that as the span changes its length the truss ends move the required amount upon the rollers. In the case of stiffened suspension bridges, however, the ends of the cables at the anchorages are rigidly fixed, so that any adjustment required by change of temperature must be consistent with the change of length of cable between the anchorages. The backstays, which are those portions of the cables extending from the anchorages to the tops of the towers, expand and contract precisely as do the portions of the cable between the tops of the towers. As the cables lengthen, therefore, the sag or rise at the centre of the main span will be due to the change in the entire length of cable from anchorage to anchorage. In order to meet this condition it is usual to support the cables at the tops of the towers on seats called saddles which rest upon rollers, so as to afford any motion that may be required. Designs have been made in which the cables are fixed to the tops of steel towers. In such cases changes of temperature would subject the towers to considerable bending which would be provided for in the design.

The rise and fall at the centres of long spans of stiffened suspension bridges is considerable; indeed, for a variation of 120° Fahr. the centre of the New York and Brooklyn Bridge changes its elevation by 4.6 feet if the saddles are free to move, as intended. In the case of a stiffened suspension bridge designed to cross the North River at New York City with a main span of 3200 feet a variation of 120° Fahr. in temperature would produce a change of elevation of the centre of the span of 6.36 feet. Such thermal motions in the structure obviously will produce stresses of considerable magnitude in various parts of the stiffening trusses, all of which are invariably recognized and provided for in good design.

=139. Formation of the Cables.=—At the present time suspension-bridge cables are made by grouping together in one cylindrical mass a large number of so-called strands or individual small cables, each composed of a large number of parallel wires about one sixth of an inch in diameter. The four cables of the New York and Brooklyn Bridge are each composed of 19 strands, each of the latter containing 332 parallel wires, making a total of 6308 wires, the cables themselves being 15½ inches in diameter. The wire is No. 7 gauge, i.e., 0.18 inch in diameter. In the new East River Bridge each of the four cables is 18¼ inches in diameter and contains 37 strands, each strand being composed of 208 wires all laid parallel to each other, or a total of 7696 wires. The size of the wire is No. 6 (Roebling) gauge, i.e., 0.192 inch in diameter. These strands are formed by laying wire by wire, each in its proper place. The strands are then bound together into a single cable, around which is tightly wound a sheathing or casing of smaller wire, 0.134 inch in diameter for the New York and Brooklyn Bridge. The tightness of this binding wire insures the unity of the whole cable, each wire having been placed in its original position so as to take a tension equal to that of each of the other wires. The suspension-rods are usually of wire cables and are attached by suitable details to the lower chords of the stiffening truss, also by specially designed clamps to the cable. The stiffening trusses are usually built with all riveted joints, so as to secure the greatest possible stiffness from end to end. The stiffened suspension bridge has been shown by experience, as well as by theory, to be well adapted to carry railroad traffic over long spans.

=140. Economical Limits of Spans.=—In the past, suspension bridges have, in a number of cases, been built for comparatively short spans, but it is well recognized among engineers that their economical use must be found for spans of comparatively great length. While definite lower limits cannot now be assigned to such spans, it is probable that with present materials of construction and with available shop and mill capacities the ordinary truss-bridge may be economically used up to spans approximately 700 to

800 feet, and that above that limit the cantilever system is economically applicable to lengths of span not yet determined but probably between 1600 and 2000 feet. The special field of economical employment of the long-span stiffened suspension bridge will be found at the upper limit of the cantilever system. So far as present investigations indicate, the stiffened suspension type of structure may be employed to advantage from about 1800 feet up to the maximum practicable length of span not yet assignable, but perhaps in the vicinity of 4000 feet. Obviously such limits are approximate only and may be pushed upward by further improvements in the production of material and in the enlargement of both shop and mill capacity.

PART III.

WATER-WORKS FOR CITIES AND TOWNS.

CHAPTER XIV.

=141. Introductory.=—A preceding lecture in this course has shown to what an advanced state the public supply of water to large cities was developed in ancient times. The old Romans, Greeks, Egyptians, and other ancient peoples evidently possessed an adequate appreciation of the value of efficient systems of public water-supply. Very curiously that appreciation diminished so greatly as almost to disappear during the middle ages. The demoralization of public spirit and the decrease of national power which followed the fall of Rome induced, in their turn, among other things, a neglect of the works of the great water system of Rome, entailing their partial destruction. The same retrogression in civilization seemed to affect other ancient nations as well, until probably the lowest state of the use of public waters and the construction of public water systems was reached somewhere between A.D. 1000 and A.D. 1300 or 1400. Without reasonable doubt the terrible epidemics or plagues of the middle ages can be charged to the absence of suitable water-supplies and affiliated consequences. During that middle period of the absence of scientific knowledge and any apparent desire to acquire it, sanitary works and consequently sanitary conditions of life were absolutely neglected. No progress whatever was made toward reaching those conditions so imperative in large centres of population for the well-being of the community. Grossly polluted waters were constantly used for public and private supplies, and no efforts whatever were made among the masses toward the suitable disposition of refuse matters or, in a word, to attain to sanitary conditions of living.

A few important works were completed, particularly in Spain, but nothing indicative of general relief from the depths of ignorance and sanitary demoralization to which the greater portion of the civilized world had sunk at that time. The city of Paris took all its water from the Seine, except that which was supplied by a small aqueduct built in 1183. So small was the supply, aside from the water obtained from the river, that in 1550 it is estimated that the former amounted to about one quart only per head of population per day. The situation in London was equally bad, for it was only in the first half of the thirteenth century that spring-water was brought to the city by means of lead pipes and masonry conduits. Public water-works began to be constructed in Germany on a small scale in the early part of the fifteenth century. Obviously no pumps were available in those early days of water-supply, so that the small systems which have been mentioned were of the gravity class; that is, the water flowed naturally in open or closed channels from its sources to the points of consumption. Pumps of a simple and crude type first began to be used at a point on the old London Bridge in 1582, and in Hanover in 1527. Subsequently to those dates other pumps were set up on London Bridge, and installations of the same class of machinery were made in Paris in 1608, usually operated by water-power in some simple manner, as by the force of the water-currents. In 1624 the Paris supply received a reinforcement of 200,000 gallons per day by the completion of the aqueduct Arcueil. The New River Company was incorporated in 1619 for the partial supply of the city of London, and it began to lay its pipes at that time. As its name indicates, it took its supply from New River, and the inception of its business is believed to mark the first application of the principle of supplying each house with water. This company is still in existence and furnishes a considerable portion of the present London supply.

=142. First Steam-pumps.=—The application of steam to the creation or development of power by Watt, near the end of the eighteenth century, stimulated greatly the construction of water-works, as it offered a very convenient and economical system of pumping. It seems probable that the first steam-pumps were used in London in 1761. Twenty years later a steam-pump was erected in Paris, while another was installed in 1783. The second steam-pump in London was probably constructed in 1787. In all these earlier instances of the use of steam-pumps river supplies were naturally used.

=143. Water-supply of Paris and London.=—After the early employment of steam pumping-machinery demonstrated its great efficiency for public water-supplies, the extension of the latter became more rapid, and since 1800 the supplies of the two great

cities of London and Paris have been greatly increased. As late as 1890 the Paris supply amounted to about 65 gallons per head of population, one fourth of which was used as potable, being drawn from springs, while three fourths, drawn from rivers, was used for street-cleaning or other public purposes. This supply, however, was found inadequate and was re-enforced in 1892 by an addition of 30,000,000 gallons per day of potable water brought to the city by an aqueduct 63 miles long. Another addition of about 15,000,000 gallons has been provided more recently.

Rather curiously the water-supply of London is afforded by eight private companies, one of which is the old New River Company already mentioned. These companies, with one exception, draw their supply mainly from the rivers Thames and Lea, all such water being filtered. The remaining company draws its water from deep wells driven into the chalk. The total population supplied amounts to about 5,500,000, the rate of supply being thus less than 45 gallons per head per day.

=144. Early Water-pipes.=—Inasmuch as the use of cast-iron for pipes was only begun about the year 1800, other materials were used prior to that date. As is well known, the pipes used in ancient water-works were either of lead or earthenware. In the eighteenth century wooden pipes made of logs with their centres bored out were used, sometimes 6 or 7 inches in diameter. As many lines of these log pipes were used as needed to conduct a single line of supply. In the earlier portion of the nineteenth century such log pipes, usually of pine or spruce, were used by the old Manhattan Company for the supply of New York City. A section of such a wooden pipe, with a bore of about 2½ inches is preserved in the museum of the Department of Civil-Engineering of Columbia University. Large quantities of such pipes were formerly used.

=145. Earliest Water-supplies in the United States.=—The earliest system of public water-supply in this country was completed for the city of Boston in 1652. This was a gravity system. It is believed that the first pumping-machinery for such a supply was set up for the town of Bethlehem, Pa., and put in operation in 1754. Subsequently water-supplies were completed for Providence, R. I., 1772, and for Morristown, N. J., in 1791; the latter has maintained a continuous existence since that date. The first use of steam pumping-machinery in this country was in Philadelphia in 1800. This machinery, curiously enough, was largely of wood, including some portions of the boiler; it was necessarily very crude and would perform with 100 pounds of coal only about one twenty-fifth or one thirtieth of what may be expected from first-class pumping-machinery at the present time. Other cities and towns soon began to follow the lead of these earlier municipalities in the construction of public water-supplies, but the principal development in this class of public works has taken place since about 1850.

It is estimated that the total population supplied in 1880 was about 12,000,000, which rose to about 23,000,000 in 1890, and it is probably not less than 50,000,000 at the present time.

=146. Quality and Uses of Public Water-supply.=—Advances in the public supplies in this country have been made rather in the line of quantity than quality. Insufficient attention has been given both to the quality of the original supply and to the character of the reservoirs in which it is gathered until within possibly the past decade. A few cities like Boston have scrutinized with care both the quality of the water and the character of the bottom and banks of reservoirs, and have spared neither means nor expense to acquire a high degree of excellence in their potable water. The same observations can be applied to a few other large cities, but to a few only. The realization of the dependence of public health upon the character of water-supply, however, has been rapidly extending, and it will doubtless be but a short time before the care exercised in collecting and preparing water for public use will be as great in this country as in Europe, where few large cities omit the filtration of public waters.

The distribution of water supplied for public use is not limited to domestic purposes, although that class of consumption controls public health so far as it is affected by the consumption of water. The applications of water to such public purposes as street-cleaning and the extinguishing of fires are of the greatest importance and must receive most careful consideration. Again, the so-called system of water-carriage in the disposal of domestic and manufacturing wastes, constituting the field of sewage-disposal, depends wholly upon the efficiency of the water-supply.

=147. Amount of Public Water-supply.=—The first question confronting an engineer in the design of public water-supply is the amount which should be provided, usually stated on the basis of an estimated quantity per head of population. This is not in all cases completely rational, but it is by far the best basis available. If the water-supply is designed for a small city or town previously supplied by wells or other individual sources, the first year's consumption will be low per head of population for the reason that many people will retain their own sources instead of taking a share of the public supply. As time elapses that portion of population decreases quite rapidly in numbers, and in a comparatively few years practically the whole population will use the public supply. In communities, therefore, where public systems have long existed and it is desired either to add to the old supply or to install new

ones, the only safe basis of estimate is the entire population.

=148. Increase of Daily Consumption and the Division of that Consumption.=—The amount of water required per head of population might naturally be assumed identical with the past consumption, but that would frequently be incorrect. It is one of the most prominent features of the history of public water-supplies in this country that the consumption per head of population has increased with great rapidity from the early years of the installation of the different systems, for reasons both legitimate and illegitimate. The daily average consumption of water from the Cochituate Works of the Boston supply increased from 42 gallons per head of population in 1850 to 107 gallons in 1893, and in the Mystic Works of the same supply the increase was from 27 gallons in 1865 to 89 gallons in 1894. Again, the daily average consumption in Chicago rose from 43 gallons per head per day in 1860 to 147 gallons in 1893, while in Philadelphia during the same period the increase was from 36 gallons per head per day to 150 gallons. In Cambridge, Mass., the increase in daily average consumption per head of population was from 44 gallons in 1870 to 70 gallons in 1894. These instances are sufficient to show that, under existing conditions, the daily consumption was increased at a rapid rate in the cities named, and they have been selected as fairly representative of the whole field. Civil engineers have made extended studies in connection with this question in a great number of cities, for it bears upon one of the most important lines of public works. It is absolutely essential to the health and business prosperity of every city that the water-supply should be abundant, safe, and adapted to the industrial and commercial pursuits of its population. It is imperative, therefore, that the division of the daily supply should be carefully analyzed. For this purpose the water-supply of a city may be, and frequently is, divided into four parts:

(1) That used for domestic purposes; (2) That used for commercial and industrial purposes; (3) That used for public purposes; (4) That part of the supply which is wasted.

1. That portion of the supply consumed for domestic purposes includes not only the water used in private residences, but in those branches of consumption which may be considered of a household character found in hotels, clubs, stores, markets, laundries, and stables, or for any other residential service. As might be expected, this branch of consumption varies largely from one city to another. The results of one of the most interesting and suggestive studies ever made in connection with this subject are given by Mr. Dexter Brackett, M. Am. Soc. C. E., in the Transactions of the American Society of Civil Engineers for 1895. In Boston the purely domestic consumption varied in different houses and apartments from 59 gallons per head per day in costly apartments down to 16.6 gallons per head per day in the poorest class of apartment. In Brookline, one of the finest suburbs of Boston, the quantity was 44.3 gallons per day. In some other cities of Massachusetts, as Newton, Fall River, and Worcester, this class of consumption varied from 6.6 gallons to 26.5 gallons per day, the latter quantity being found at Newton in some of the best residences, and the former at houses also in Newton having but one faucet each. In Yonkers, N. Y., where the system was metered, the amount was 21.4 gallons per head of population per day, while in portions of London, England, it varied from 18.6 to 25.5 gallons per head per day. The average of these figures gives a result of 18.2 gallons per head per day, which, in round numbers, may be put at 20 gallons.

2. It is obvious that the rate of consumption for commercial and industrial purposes in any city must vary far more than that for domestic purposes, for the reason that some cities may be essentially residential in character while others may be essentially manufacturing. At the same time, it is to be remembered that many manufacturing establishments may have their own water-supply. The city of Fall River, Mass., is eminently a manufacturing city, yet Mr. Brackett found that the manufacturing demand on the public water-supply amounted to 2 gallons only per inhabitant per day, as the manufacturers draw the most of their supply from the river, but that where the manufacturers depend upon the public supply for all their water the amount rises to a value between 20 and 30 gallons per inhabitant. In Boston in 1892 the water consumed for all manufacturing and industrial purposes, including railroads, gas-works, elevators, breweries, etc., amounted to 9.24 gallons per head of population per day, while in Yonkers in 1897 the total consumption for commercial purposes was 27.4 gallons per head per day. In the city of New York, as nearly as can be estimated, the consumption for commercial purposes is probably not far from 25 gallons per inhabitant per day. Reviewing all these results, it may be stated that the water consumption for commercial and industrial purposes will generally range from 10 to 30 gallons per inhabitant per day.

3. The consumption of water for public purposes is a smaller amount than either of the two preceding. It covers such uses as public buildings, schools, street-sprinkling, sewer-flushing, fountains, fires, and other miscellaneous objects, more or less similar to those just named. The total use of this character was 3.75 gallons per inhabitant per day for Boston in 1892, and 5.57 gallons per inhabitant per day for Fall River in 1899. A few other cities give the following results: Minneapolis in 1897, 5 gallons; Indianapolis, 3 gallons; Rochester, N. Y., 3 gallons; Newton, Mass., 4 gallons; Madison, Wis., 10 gallons. In Paris it is estimated that not far from 2.5 gallons per head of population per day are used. It is probable, therefore, that an amount of 5 gallons per day per inhabitant will

cover this particular line of consumption.

4. A substantial portion of the water-supply of every city fails to serve any useful purpose, for the reason that it runs to waste either by intention or by neglect. The sources of this waste are defective plumbing, including leaky faucets and cocks; deliberate omission to close faucets and cocks, constituting wilful waste; defective or broken mains, including leaky joints; and waste to prevent freezing.

=149. Waste of Public Water.=—All these wastes except the last are inexcusable. There is no difficulty in detecting defective plumbing, and its existence is generally known to the householder; but if the wasted water is not measured and paid for, it is far too frequently considered more economical to continue the waste than to pay for the plumber's services. In a multitude of cases cocks are left open indefinitely for all sorts of insignificant reasons; in closets, under the erroneous impression that the continuous running of the stream will materially aid in a more effective cleansing of soil- and sewer-pipes, failing completely to appreciate that a far more powerful stream is required for that purpose; sometimes in sinks, for refrigerating purposes, and in many other inexcusably wrong ways. These sources of wilful waste lead to large losses and constitute one of the most unsatisfactory phases of administration of a public water system. Such losses result in a vicious waste of public money. The amount of water flowing from leaky joints and from leaks in pipes and mains is necessarily indeterminate because it escapes without evidence at the surface except in rare cases. In every instance where examinations have been made and a careful record kept of the amount of water supplied to a city, it has been found that the aggregate of the measured amounts consumed fail nearly to equal the total supply. There are probable errors both in the measurement of the quantities supplied and in the quantities consumed, but the large discrepancy cannot be accounted for in this manner. In many cases consumed water has even been carefully measured by meters, as at Yonkers, New York, Newton, Milton, and Fall River, Mass., Madison, Wis., and at other places, but yet the discrepancy appears to be nearly as wide as ever. Again, in 1893 observations were carefully made on the consumption of the water received by the Mystic supply of the Boston system at _all_ hours of the twenty-four. Obviously between 1 and 4 A.M. the useful consumption should be nearly nothing, but, on the contrary, it was found to be nearly 60 per cent of the average hourly consumption for the entire twenty-four hours. The waste at Buffalo, N. Y., in 1894 was estimated at 70 per cent of the total supply. Similar observations in other places have given practically the same results. It has also been found that, in a number of instances, where old watercourses have been completely obliterated by considerable depths of filling required by the adopted grades of city streets and lots, and excavations for buildings have subsequently been opened practically the full volume of the former streams are flowing along the original but filled channel. This result has been observed under a practically impervious paved city surface. It is difficult to imagine the source of such a supply except from defective pipe systems or sewers. A flow of a least 100,000 gallons per day from a broken pipe which found its way into a sewer has also been discovered without surface evidence. These and many other results of experience conclusively demonstrate that much water flows to waste unobserved from leaky joints and defective or broken pipes.

Inasmuch as cast-iron water-pipes are produced in lengths which net 12 feet as laid, there will be at least 440 joints per mile. Furthermore, as leaky joints and broken pipes are as likely to occur at one place as another, it seems reasonable to estimate leakage through them as proportionate to the length of the pipe-line in a system; and that conventional law is frequently assumed. New pipe-lines have sometimes shown a leakage of 500 to 1200 gallons per mile of line per day. Civil engineers have sometimes specified the maximum permissible leakage of a new pipe-line at 60 to 80 gallons per mile of line per day for each inch in diameter of pipe, thus permitting 600 to 800 gallons to escape from a 10-inch pipe. In 1888 the late Mr. Chas. B. Brush reported a leakage of about 6400 gallons per mile per day from a practically new 24-inch cast-iron main, 11 miles long, of the Hackensack Water Company, the pressure being 110 pounds per square inch. Tests of water-pipes in German and Dutch cities have been reported as showing less waste than 300 gallons per mile per day, but such low results, unless for very low pressures and short lines, may reasonably be doubted. Obviously losses of this character will probably increase with the age of the pipe. By a very ingenious procedure based upon his own experience, Mr. Emil Kuichling of Rochester, N. Y., reaches the conclusion that a reasonable allowance for the waste from leaky joints and defective pipes is 2500 to 3000 gallons per mile of cast-iron pipe-line per day. If, as is frequently the case, the population per mile of pipe ranges from 300 to 1000, the preceding allowance amounts to 3 to 10 gallons per head of population per day. The loss or waste due to running cocks or faucets to prevent freezing cannot be estimated with sufficient accuracy to receive a definite valuation, but it must be considered an element of the total item of waste.

=150. Analysis of Reasonable Daily Supply per Head of Population.=—It has repeatedly been found that the losses or wastes set forth in the preceding statements amount apparently to quantities varying from 30 to 50 per cent of the total supply; or, to put it a little differently, the water unaccounted for in even the best systems now constructed apparently may reach one third to one half of

the total supply. This is an exceedingly wasteful and unbusinesslike showing. It is probable that the statement is, to some extent at least, an exaggeration. It is practically certain that either the amount supplied or the amounts consumed, or both, are never measured with the greatest accuracy, and that the errors are such as generally swell the apparent quantity wasted. After making judicious use of the data thus afforded by experience, it is probable that the following tabular statement given by Messrs. Turneaure and Russell represents limits within which should be found the daily average supply of water in a well-constructed and well-administered system.

+----------+----------+ | | Gallons per Head per Day. | | Use. +----------+----------+----------+ | | Minimum. | Average. | Maximum. | +----------+----------+----------+----------+ | Domestic | 15 | 25 | 40 | | Industrial and commercial | 5 | 20 | 35 | | Public | 3 | 5 | 10 | | Waste | 15 | 25 | 30 | +----------+----------+----------+----------+ | Total | 38 | 75 | 115 | +----------+----------+----------+----------+

The values given in the preceding table are reasonable and sufficient to supply the legitimate needs of any community, but, as will be shown in the succeeding table, there are cities in this country whose average consumption is more than twice the maximum rate given above.

=151. Actual Daily Consumption in Cities of the United States.=—The following table exhibits the average daily consumption of water throughout the entire year for the cities given, as determined for the years indicated in the table.

The city of Buffalo shows a daily consumption of 271 gallons per inhabitant, and Allegheny, Pa., 247 gallons per inhabitant. There are a considerable number showing an average daily consumption per inhabitant of 160 gallons or more. All such high averages exhibit extravagant use of water, or otherwise inefficient administration of the water-supply. The reduction of such high rates of consumption is one of the most difficult problems confronting the administration of public works. The use of the meter has proved most efficient in preventing wastes or other extravagant consumption, as in that case every consumer pays a prescribed rate for the amount which he takes.

TABLE I.

[4] Estimated.

=152. Actual Daily Consumption in Foreign Cities.=—It has been for a long time a well recognized fact that the daily use of water in American municipalities is far greater per inhabitant than in European cities. It is difficult to explain the marked difference, but it is probably due in large part to the more extravagant general habits of the American people. Examinations in a number of cases have shown that the actual domestic use of water, at least in some of the American cities, is not very different from that found in corresponding foreign cities. Table II exhibits the consumption of water in European cities, as compiled from various sources and given by Turneaure and Russell.

TABLE II.

----------+----------+---------- | |Consumption | Estimated | per Capita City. | Population. | Daily, | | Gallons. ----------+----------+---------- England, 1896-97:[5] | | London | 5,700,000 | 42 Manchester | 849,093 | 40 Liverpool | 790,000 | 34 Birmingham | 680,140 | 28 Bradford | 436,260 | 31 Leeds | 420,000 | 43 Sheffield | 415,000 | 21 Nottingham | 272,781 | 24 Brighton | 165,000 | 43 Plymouth | 98,575 | 59 Germany, 1890 (Lueger): | | Berlin | 1,427,200 | 18 Breslau | 330,000 | 20 Cologne | 281,700 | 34 Dresden | 276,500 | 21 Düsseldorf | 144,600 | 25 Stuttgart | 139,800 | 26 Dortmund | 89,700 | 78 Wiesbaden | 62,000 | 20 France, 1892 (Bechmann): | | Paris | 2,500,000 | 53 Marseilles | 406,919 | 202 Lyons | 401,930 | 31 Bordeaux | 252,654 | 58 Toulouse | 148,220 | 26 Nantes | 125,000 | 13 Rouen | 107,000 | 32 Brest | 70,778 | 3 Grenoble | 60,855 | 264 Other countries, 1892-96 (Bechmann): | | Naples | 481,500 | 53 Rome | 437,419 | 264 Florence | 192,000 | 21 Venice | 130,000 | 11 Zurich | 80,000 | 60 Geneva | 70,000 | 61 Amsterdam | 515,000 | 20 Rotterdam | 240,000 | 53 Brussels | 489,500 | 20 Vienna | 1,365,000 | 20 St. Petersburg | 960,000 | 40 Bombay | 810,000 | 61 Sidney | 423,600 | 38 Buenos Ayres | 680,000 | 34 ----------+----------+----------

[5] Compiled, except the figures for London, by Hazen. _Engineering News_, 1899, XLI. p. 111.

These foreign averages, with three exceptions, represent reasonable quantities of water used, and they have been confirmed as reasonable by many special investigations made in this country.

=153. Variations in Rate of Daily Consumption.=—The preceding observations are all based upon an average total consumption found by dividing the total annual consumption by the number of days in the year. This is obviously sufficient in a determination of the total supply needed, but it is not sufficient in those matters which involve a rate of supply during the different hours of the day, or the amount of the supply for the summer months as compared with those of the winter. As a general rule the greatest supply will be required during the hot summer months when lawn- and street-sprinkling is most active. It appears from observations made in a considerable number of the large cities of the United States that the maximum monthly average consumption may run from about 110 to nearly 140 per cent of the monthly average throughout the year. As an approximate value only, it may be assumed for ordinary purposes that the maximum monthly demand will be 125 per cent of the average.

The daily rate taken throughout the year is considerably more variable than the monthly. There are days in some portions of the year when consumption by hotels and industrial activities is at a minimum. On the other hand, there are other days when those activities are at a maximum and the total draft will be correspondingly high. Experience has shown that the maximum total draft may vary from about 115 to nearly 200 per cent of the average. It is permissible, therefore, to take approximately for general purposes the maximum total daily consumption as 150 per cent of the average. Manifestly any total consumption will have an hourly rate which may vary greatly from the early morning hours, when the draft should be almost nothing, to the forenoon hours on certain days of the week, when the draft is a maximum. These variations have frequently been investigated, and it has been shown that the maximum rate per hour of a maximum day may sometimes rise higher than 300 per cent of the average hourly rate for the year. These considerations obviously attain their greatest importance in connection with the capacity of the plant, either power or gravity, from which the city directly draws its supply. The hourly capacity of the pumps or steam-plant furnishing the supply need not necessarily be equal to the maximum, since storage-reservoirs may be and usually are used; but the capacity of the pipe system leading from such storage-reservoirs must be equal to the maximum hourly rate required.

=154. Supply of Fire-streams.=—The draft on a water-supply for fire-extinguishing purposes may have an important influence upon the hourly rate of consumption. These observations are particularly pertinent in connection with the water-supply of small cities where the draft of fire-engines may be considered a large percentage of the total hourly consumption. It is obviously impossible to

assign precisely the number of fire-streams which may be required simultaneously in a city having a given population, but experiences of a considerable number of civil engineers furnish reasonable bases on which such estimates may be made. Table III exhibits such estimates as made by the civil engineers indicated. It is given by Mr. Emil Kuichling in the Transactions of the American Society of Civil Engineers for December, 1897. Probably no more reasonable estimate can be now presented.

TABLE III.

TABLE EXHIBITING ESTIMATED NUMBER OF FIRE-STREAMS REQUIRED SIMULTANEOUSLY IN AMERICAN CITIES OF VARIOUS MAGNITUDES.

---------- | Number of Fire-streams Required Simultaneously. Population of Community. | 1 | 2 | 3 | 4 | Freeman. | Shedd. | Fanning. | Kuichling. 1,000 | 2 to 3 | .. | .. | 3 4,000 | .. | .. | 7 | 6 5,000 | 4 to 8 | 5 | .. | 6 10,000 | 6 to 12 | 7 | 10 | 9 20,000 | 8 to 15 | 10 | .. | 12 40,000 | 12 to 18 | 14 | .. | 18 50,000 | .. | .. | 14 | 20 60,000 | 15 to 22 | 17 | .. | 22 100,000 | 20 to 30 | 22 | 18 | 23 150,000 | .. | .. | 25 | 34 180,000 | .. | 30 | .. | 38 200,000 | 30 to 50 | .. | .. | 40 250,000 | .. | .. | .. | 44 300,000 | .. | .. | .. | 48

The discharge of each fire-stream will of course vary with its diameter and the pressure at the fire-engine, but as an average it is reasonable to assume that each stream will discharge 250 gallons per minute. The quantity of water required, therefore, to supply the estimated number of streams given in Table III is found by simply multiplying the number of those streams by 250, to ascertain the total number of gallons consumed per minute. If _x_ is the number of thousand inhabitants in any city, and if _y_ represents the required number of streams, then Mr. Kuichling deduces the following formulæ for _y_ by the use of the preceding tables, i.e., these formulæ express the results given in the preceding table as nearly as simple forms of formulæ permit. $y = 1.7\sqrt{x} + 0.033x$ For Freeman's data: $y_{max.} = \frac{x}{5} + 10$. (1) $y_{min.} = \frac{x}{10} + 9$. (2)

For Fanning's data: $y = 2.8\sqrt{x}$. (3)

For Shedd's data: $y = \sqrt{5x} = 2.24\sqrt{x}$. (4)

For the author's data: $y = 2.8\sqrt{x}$. (4)

While for the average ordinary consumption of water, expressed in gallons per head and day, _q_, Mr. Coffin's formula, as given in his paper previously cited, may be taken

$$q = 40x^{\frac{1}{10}}. \quad (5)$$

By combining equation (5) with equation (4), remembering that the maximum rate of consumption is usually about 1.5 times the average, the total draft in gallons per minute upon the discharging system at the time of a conflagration will become as follows:

$$Q = 250(2.8\sqrt{x}) + \frac{40 \times 1000}{1440}x^{\frac{1}{10}}$$

$$= 250\left(2.8\sqrt{x} + \frac{x^{\frac{1}{10}}}{6}\right) \quad (6)$$

This maximum rate of consumption during a conflagration does not affect the total supply of a large city like New York, Boston, or Chicago, but it may become of relatively great importance in a small city or town. In a large city this draft may and frequently does tax the capacity of a small district of the discharging system. In designing such systems, therefore, even for large cities, it is necessary to insure all districts against a small local supply when a large one may pressingly be needed.

CHAPTER XV.

=155. Waste of Water, Particularly in the City of New York.=—The quantity of water involved in designing a water-supply for cities and towns is much larger than that which is actually needed. The experience of civil engineers in many cities, both in this country and in Europe, shows conclusively that the portion of water actually wasted or running away without serving any purpose will usually run from 30 to 50 per cent of the total amount brought to the distributing system. In the city of New York there is strong reason to believe that the wastage is not less than two thirds of the total quantity supplied. It is frequently assumed that both the quantities supplied and the quantities uselessly wasted in New York are larger than in other places. As a matter of fact those quantities are actually smaller than in some other large cities. While the supply per inhabitant in New York City is much larger than should be required, the use of water by its citizens is not extravagant when gauged by the criterion of use in other large cities. This question was most carefully and exhaustively investigated in 1899 and the early part of 1900 by Mr. John R. Freeman of Boston, acting for the comptroller of the city of New York.

The usual wastes of a water-supply system may be distributed under six principal heads. First, leaky house-plumbing; second, and “possibly first in order of magnitude,” leaky service-pipes connecting the house pipe system with street-mains; third, leaving water-cocks open unnecessarily; fourth, leaky joints in street-mains or pipes; fifth, possibly pervious beds and banks of distributing-reservoirs; sixth, stealing or “unlawful diversion” of water through surreptitious connections.

The sixth item is probably an extremely small one in New York, although instances of that kind of waste have been found. It is an old wastage known as far back in time as the ancient Roman water-supply. The second and third items probably constitute the bulk of the wastage in this city.

=156. Division of Daily Consumption in the City of New York.=—In the course of his search for the various sources of consumption, Mr. Freeman concluded from his examinations and from the use of the various means placed at his command for measuring the daily consumption between December 2nd and December 5th, 1899, and December 8th and December 15th, 1899, that the average daily consumption could be divided as follows:

Gallons per Inhabitant per Day.

Probable average amount really used 40 Assumed incurable waste 10} Curable waste, probably 65} 75 ---- Daily uniform rate of delivery by Croton Aqueduct 115

In his investigations Mr. Freeman had the elevation of water in the Central Park reservoir carefully observed every six minutes throughout the twenty-four hours. At the same time the uniform flow through the new Croton Aqueduct was known as accurately as the flow through such a conduit can be gauged at the present time. Knowing, therefore, the concurrent variation of volume in the Central Park reservoir supplied by the new Croton Aqueduct and the rate of flow in that aqueduct, the consumption of water per twenty-four hours would be known with the same degree of accuracy with which the flow in the aqueduct is measured. It was found by these means that the actual consumption between the hours of 2 and 4 A.M. was at the rate of 94 gallons per inhabitant per day, although the actual use at that time was as near zero as it is possible to approach during the whole twenty-four hours. Nearly all of that rate of consumption represents waste.

Summing up the whole matter in the light of his investigations, Mr. Freeman made the following as his nearest estimate to the actual consumption of the daily supply of water of New York City:

Gallons per Inhabitant ACTUAL USE: per Day. Domestic (average) 12 - 20 Manufacturing and commercial 20 - 30 City buildings, etc. 2 - 4 Fires, street flushing and sprinkling 0.4 - 0.7 ---------- Total 34 - 55

INCURABLE WASTE (probabilities): Leaks in mains 1 - 2 Leaks in old and abandoned service-pipes 1 - 2 Poor plumbing, all taps metered and closely inspected 2 - 3 Careless and wilful wastes 1 - 2 Under-registry of meters 1 - 1 ------- Total incurable waste and under-registry 6 -10 ======== Minimum use and waste 40 -65

NEEDLESS WASTE: Leaks in street-mains (a guess) 15- 10 Leaks in service-pipes between houses and street-mains 15- 10 (a guess) Defective plumbing (a guess) 25- 15 Careless and wilful opening of cocks (a guess) 17- 14 To prevent freezing in winter and for cooling in summer 3 - 1 -------- Total needless waste 75- 50 ======== Total consumption 115-115

=157. Daily Domestic Consumption.=—The quantity assigned in the preceding statement to domestic use is confirmed by the abundant experience in other cities where services are carefully metered, as in Fall River, Lawrence, and Worcester, Mass., and in Woonsocket, R. I., where measurements by meters show that the domestic consumption has varied from 11.2 to 16.3 gallons per inhabitant per day. Furthermore, annual reports of the former Department of Public Works and the present Department of Water-supply for the City of New York show that during the years 1890 to 1898 such meters as have been used in the territory supplied by the Croton and the Bronx aqueducts indicate a daily consumption varying from 13.8 to 24.2 gallons per inhabitant per day. The same character of confirmatory evidence can be applied to the quantities assigned to manufacturing and commercial uses, city buildings and fires, street flushing and sprinkling.

=158. Incurable and Curable Wastes.=—The items composing incurable waste, unfortunately, cannot be so definitely treated. It is perfectly well known, however, among civil engineers, that a large amount of leakage takes place from corporation cocks, which are those inserted in the street-mains to form the connection between the latter and the house service-pipes. Again, many of these service-pipes are abandoned and insufficiently closed, or not closed at all, leaving constantly running streams whose continuous subsurface discharges escape detection and frequently find their way into sewers. Water-pipes which have been laid many years

frequently become so deeply corroded as to afford many leaks and sometimes cracks. Doubtless there are many portions of a great distributing system, like that in New York City, which need replacing and afford many large leaks, but undiscoverable from the surface. Many lead joints of street-mains also become leaky with age, while others are leaky when first laid in spite of inspection during construction. Just how much these items of waste would aggregate it is impossible accurately to state, but from careful observations made in other places 5 to 10 gallons per day per head of population seems reasonable. A three-year-old cast-iron fire-protection pipe 5.57 miles long and mainly 16 inches in diameter, under an average pressure of 114 pounds per square inch, was tested in Providence in 1900 and showed a leakage at lead joints only of 446 gallons per mile per twenty-four hours, which was equivalent to .22 gallon per foot of lead joint per twenty-four hours. Further tests in 1900 of seven lines of new pipe laid by the Metropolitan Board of Boston, and tested under pressures varying from 50 to 150 pounds per square inch by Mr. F. P. Stearns, chief engineer, and Mr. Dexter Brackett, engineer of Distribution Department, and having an aggregate length of 51.4 miles with diameters ranging from 16 to 48 inches, gave an average leakage per lineal foot of pipe in gallons per twenty-four hours ranging from .6 to 3.7 gallons (average 2.47 gallons), equivalent to an average leakage of 3 gallons per twenty-four hours per lineal foot of lead joint. The possible rates of leakage from street-mains are to be applied to a total length of pipe-lines of 833 miles for the boroughs of Manhattan and the Bronx. The borough of Brooklyn has somewhat over 600 miles of street-mains, but they are not to be considered in connection with the Croton and Bronx water-supply.

All these considerations either confirm or make reasonable the estimates of the various items of actual use and waste set forth by Mr. Freeman.

=159. Needless and Incurable Waste in City of New York.=—Concisely summing up his conclusions, it may be stated that in the year 1899 the average consumption per inhabitant of the boroughs of Manhattan and the Bronx was 115 gallons; of these 115 gallons the needless average waste may be 65 gallons, while the incurable or necessary waste may probably be taken at 10 gallons per inhabitant per day. It is further probable that the total underground leakage in New York City is to be placed somewhere between 20 to 35 gallons per inhabitant per day.

=160. Increase in Population.=—The total volume of daily supply to any community is determined by the population; but the population is as a whole constantly increasing. It becomes necessary, therefore, to estimate the capacity of a water-supply system in view of the future population of the city to be supplied. No definite rule can be set as to the future period for which the capacity of any desired system is to be estimated. It may be stated that no shorter period of time than probably ten years should be considered, indeed it is frequently prudent to provide for a period of not less than twenty years, and it may sometimes be necessary or advisable to consider a possible source of supply for even fifty years. Provision must be made not only for the present population, but for the increase during those periods of time, or at least for the possible development that may be needed.

The increase in population of cities will obviously vary for different locations with the character of the occupations followed and with the development of such important factors of industrial life as railroad connections, facilities for marine commerce, the capacity for development of the surrounding country, and other influences which aid in the increase of commerce and industrial activity and the growth of population. It has been observed, as a matter of experience, that large cities generally reach a point where their subsequent increase of population is represented by a practically constant percentage, the value of that percentage depending upon local considerations. In 1893, when it was desired to estimate the future population of London for as much as forty years, it was found that the increase for the ten years from 1881 to 1891 was 18.2 per cent, with an average of about 20 per cent for several previous decades. It could, therefore, be reasonably estimated for the city of London that its population at the end of any ten-year period would be 18.2 per cent greater than its population at the beginning of that period. In Appendix 1 of the report of the Massachusetts State Board of Health upon the Metropolitan water-supply for the city of Boston made in 1895, the increases for the two ten-year periods 1870-1880 and 1880-1890 were 6 per cent and 9.6 per cent respectively for the city proper, but for the population within a ten-mile radius from the centre of the city they were 28.7 per cent and 33.7 per cent respectively. The corresponding percentages for the cities of New York, Philadelphia, and Chicago for the same periods are as shown in the following tabular statement:

Population.	Percentages of Increase.
1870.	1880.	1890.	1870-80.	1880-90.
New York	1,626,119	2,131,051	2,821,802	31	32
Philadelphia	726,247	921,458	1,162,577	27	26
Chicago	310,996	550,618	1,075,158	77	95[6]

---

[6] Includes added territory.

Obviously every estimate of this kind must be made upon the merits of the case under consideration. The probable increase of population for any particular city is sometimes estimated by considering the circumstances of growth of some other city of practically the same size, and if possible with the same commercial industries or residential environment, or making suitable allowances for variations in these respects. Since it is imperative to secure as accurate estimates as practicable, both methods or other suitable methods should be employed, in order that the results may be confirmed or modified by comparison. In every case the supply system should be designed to meet reasonable estimated requirements for the longest practicable future period, preferably not less than twenty years.

=161. Sources of Public Water-supplies.=—One of the most important features of a proposed water-supply is its source, since not only the potable qualities are largely affected by it, but frequently the amount also. The two general classes into which potable waters are divided in respect to their sources are surface-waters and ground-waters. Surface-waters include rain-water collected as it falls, water from rivers or smaller streams, and water from natural lakes; they are collected in reservoirs and lakes or impounding reservoirs. Ground-waters are those collected from springs, from ordinary or shallow wells, from deep or artesian wells, and from horizontal galleries, like those sometimes constructed near and parallel to subsurface streams or in subsurface bodies of water, affording opportunity for filtration from the latter through sand or other open materials to them.

The quality of water will obviously be affected by the kind of material through which it percolates or flows. Surface-waters, flowing over the surface of the ground or percolating but a short distance below the surface, naturally have contact with vegetable matter, unless they are collected in a country where the soil is sandy and where the vegetation is scarce. If such waters flow through swamps or over beds of peat or other similar vegetable mould or soil, they may become so impregnated with organic matter or so deeply colored by it that they are not available for potable purposes. Ground-waters, on the other hand, possess the advantage of having flowed through comparatively great depths of sand or other earthy material essentially free of organic matter. They may, however, in some locations, carry prejudicial amounts of objectionable salts in solution, rendering them unfit for use. As a rule, ground-waters are apt to be of better quality than surface-waters, but they do not generally stand storage in reservoirs as well as surface potable waters. It is advisable to store them in covered reservoirs from which the light is excluded, rather than in open reservoirs. They are sometimes impregnated with salts of iron to such an extent as to make it necessary to resort to suitable processes for their removal, and they are also occasionally found so hard as to require the employment of methods of softening them.

Both sources of supply are much used in the United States. Table IV shows the percentages of the various classes of supplies as found in this country during the year 1897; the total number of supplies having been at that time nearly 4000.

TABLE IV.

WATER-SUPPLIES OF THE UNITED STATES.

Source. Per Cent of Total.

{Rivers 25 Surface-waters: {Lakes 7 {Impounding reservoirs 6 {Combinations .5 ----- 38.5

{Shallow wells 26 {Artesian wells 10 Ground-waters: {Spring 15 {Galleries and tunnels 1 {Combinations 2 ----- 54

Surface- and {Rivers and ground-waters 6 ground-waters: {Lakes and ground-waters 1 {Impounding reservoirs and ground-waters .5 ---- 7.5 ------- Total 100.0

It will be observed that a little more than one half of the supplies are from ground-waters. The practice in connection with European public water-supplies is different in that a considerably larger percentage of the total is taken from ground-waters.

The original source of essentially all the water available for public water-supplies is the rainfall. It becomes of the greatest necessity, therefore, to secure all possible information regarding rainfall wherever it may be necessary to construct a public water-supply. Civil engineers and other observers have for many years maintained continuous records of rainfall observations at various points throughout the country, but it is within only a comparatively short time that the number of those points has been large. Through the extension of the work of the Weather Bureau, points of rainfall observation are now scattered quite generally throughout all States of the Union. The oldest observations are naturally found in connection with stations located in the Eastern States, where the rainfall is more uniformly distributed than in many other portions of the country. Obviously rainfall records become of the greatest importance in those localities like the semiarid regions of the far West where long periods of no rain occur.

=162. Rain-gauges and their Records.=—The instrument used for the collection of rain in order to determine the amount falling in a given time is the rain-gauge, which may be fitted with such appliances as to give a continuous record of the rate of rainfall. It has been found that the location of the rain-gauge has a very important influence upon the amount of rain which it collects. It should be placed where wind currents around high structures in its vicinity cannot affect its record. The top of a large flat-roofed building is a good location in a city, although the elevation above the surface of the ground, as is well known, affects the quantity of water collected by the gauge. The collection will be greater at a low elevation than at a high one, in consequence of the greater wind currents at the higher point, it being well known that less rain will be collected where there is the most wind, other things being equal.

[Illustration: Ordinary Rain-gauge.]

=163. Elements of Annual and Monthly Rainfall.=—In consequence of the great variations in the rate of rainfall, not only for different portions of the country, but at different times during the same storm, it becomes necessary to determine various quantities such as the maximum, minimum, and mean annual rainfall, the actual monthly rainfall for different months of the year, and the maximum and minimum monthly rainfall for as long a period as possible. The minimum monthly rainfall and the minimum annual rainfall are of special importance in connection with public water-supply and water-power questions, since those minima will, in connection with the area of a given watershed, determine the greatest amount of water which can be made available for use. In entering upon the consideration of such questions, therefore, civil engineers must inform themselves with the greatest detail as to the characteristics of the monthly and the annual rainfall of the locality in which their works are to be located.

[Illustration: MONTHLY VARIATIONS IN RAINFALL.

FIG. 1.]

TABLE V.

GENERAL RAINFALL STATISTICS FOR THE UNITED STATES.

---------- | | Per Cent| | | of | Per Cent | Mean | Summer | Driest Station. | Yearly | and | Year to |Rainfall.| Autumn | Mean | | Rain to| Year. | | Mean | | | Yearly. | ---------- North Atlantic: | | | Boston | 45.4 | 50 | 60 New York | 44.7 | 52 | 62 Philadelphia | 42.3 | 52 | 70 Washington | 42.9 | 51 | 69 South Atlantic: | | | Wilmington | 53.7 | 61 | 75 Charleston | 49.1 | 61 | 48 Augusta | 48.0 | 50 | 81 Jacksonville | 54.1 | 65 | 74 Key West | 38.2 | 70 | 54 Gulf and Lower Mississippi: | | | Montgomery | 52.5 | 42 | 76 Mobile | 62.6 | 51 | 68 New Orleans | 60.3 | 52 | 64 Galveston | 47.7 | 58 | 50 Nashville | 50.2 | 46 | 67 Ohio Valley: | | | Pittsburg | 36.6 | 53 | 70 Cincinnati | 42.1 | 50 | 60 Indianapolis | 42.2 | 51 | 59 Cairo | 42.6 | 47 | 62 Louisville | 47.2 | 48 | 74 Lake Region: | | | Detroit | 32.5 | 56 | 65 Cleveland | 36.6 | 54 | 71 Duluth | 30.7 | 63 | 65 Upper Mississippi Valley: | | | St. Louis | 40.8 | 52 | 55 Chicago | 34.0 | 54 | 66 Milwaukee | 31.0 | 55 | 66 Madison | 33.2 | 58 | 39 The Plains: | | | Omaha | 31.4 | 63 | 57 North Platte | 18.1 | 61 | 56 Denver | 14.3 | 48 | 59 Cheyenne | 12.7 | 55 | 39 The Plateau: | | | Tucson | 11.7 | 65 | 44 Santa Fé | 14.6 | 69 | 53 Salt Lake City | 18.8 | 39 | 55 Walla Walla | 15.4 | 38 | 46 Pacific Coast: | | | Astoria | 77.0 | 33 | 64 Portland | 46.2 | 31 | 67 Sacramento | 19.9 | 16 | 42 San Francisco | 23.4 | 17 | 51 Los Angeles | 17.2 | 15 | 33 San Diego | 9.7 | 18 | 30 ---------- | | | | | | Per Cent| Per Cent| Number Station. | Two | Three | of | Driest | Driest | Years' | Years. | Years. | Record. | | | | | ---------- North Atlantic: | | | Boston | 70 | 80 | 79 New York | 77 | 80 | 61 Philadelphia | 75 | 80 | 72 Washington | 71 | 74 | 45 South Atlantic: | | | Wilmington | 80 | 81 | 26 Charleston | 55 | 62 | 89 Augusta | 88 | 87 | 27 Jacksonville | 77 | 83 | 27 Key West | 61 | 73 | 49 Gulf and Lower Mississippi: | | | Montgomery | 80 | 83 | 24 Mobile | 75 | 78 | 26 New Orleans | 75 | 77 | 26 Galveston | 65 | 72 | 26 Nashville | 73 | 83 | 32 Ohio Valley: | | | Pittsburg | 78 | 85 | 54 Cincinnati | 72 | 71 | 62 Indianapolis | 76 | 82 | 27 Cairo | 75 | 81 | 25 Louisville | 81 | 85 | 25 Lake Region: | | | Detroit | 72 | 79 | 46 Cleveland | 74 | 81 | 41 Duluth | 81 | 88 | 26 Upper Mississippi Valley: | | | St. Louis | 65 | 75 | 60 Chicago | 80 | 86 | 30 Milwaukee | 74 | 73 | 53 Madison | 58 | 68 | 28 The Plains: | | | Omaha | 63 | 70 | 27 North Platte | 67 | 72 | 22 Denver | 71 | 77 | 27 Cheyenne | 62 | 75 | 27 The Plateau: | | | Tucson | 79 | 80 | 19 Santa Fé | 63 | 66 | 37 Salt Lake City | 64 | 74 | 29 Walla Walla | 81 | 86 | 27 Pacific Coast: | | | Astoria | 68 | 77 | 34 Portland | 76 | 79 | 27 Sacramento | 67 | 84 | 47 San Francisco | 73 | 78 | 47 Los Angeles | 48 | 59 | 24 San Diego | 54 | 61 | 47 ---------- ---------- ---------- ----------

The diagram Fig. 1 and Table V are constructed from data given in the bulletins of the Weather Bureau and exhibit some of the general features of the rainfall for different points throughout this country. The heavy lines of the diagram show the average monthly precipitation at the points indicated, for periods of a considerable number of years, as shown in the table. It will be observed that the rainfall is comparatively uniform in the North Atlantic States but quite variable on the Pacific coast, as well as in the Mississippi and

Missouri valleys and west of those valleys.

=164. Hourly or Less Rates of Rainfall.=—Although not often of great importance in connection with public water-supply systems, it is sometimes necessary to possess data regarding maximum hourly (or less) rates of precipitation in connection with sewer or drainage work. The earlier records give exaggerated reports of maximum rates of rainfall, although that rate varies rapidly with the time. Throughout a rain-storm the rate of precipitation is constantly varying and the maximum rate seldom if ever extends over a period equal to a half-hour; usually it lasts but a few minutes only. In this country an average rate of 1 inch per hour, extending throughout one hour, is phenomenal, although that rare amount is sometimes exceeded. A maximum rate of about 4 inches per hour, lasting 15 to 30 minutes, is, roughly speaking, about as high as any precipitation of which we have reliable records. The waste ways or other provisions for the discharge of surplus or flood-waters of the Metropolitan Water-supply of Boston are designed to afford relief for a total precipitation of 6 inches in twenty-four hours. It is safe to state that an excess of that accommodation will probably never be required.

=165. Extent of Heavy Rain-storms.=—In all engineering questions necessitating the consideration of these great rain-storms it is necessary to remember that their extent is frequently much greater than the areas of watersheds usually contemplated in connection with water-supply work. The late Mr. James B. Francis found in the great storm of October, 1869, which had its maximum intensity in Connecticut, that the area over which 6 inches or more of rain fell exceeded 24,000 square miles, and that the area over which a depth of 10 inches or more fell was 519 miles. Again, in the New England storm of February, 1886, 6 inches or more of rain fell over an area of at least 3000 square miles. Storm records show that as much as 8 or 10 inches in depth have fallen over areas ranging from 1800 to 500 square miles, respectively, in a single storm.

=166. Provision for Low Rainfall Years.=—The capacity of any public water-supply must evidently be sufficient to meet not only the general exigencies of the year of lowest rainfall, but also the conditions resulting from the driest periods of that year. It is customary among civil engineers to consider months as the smaller units of a dry year. It is necessary, therefore, to examine not only the annual rainfalls but the monthly rates of precipitation during critical years, i.e., usually during dry years.

It is impossible to determine absolutely the year of least rainfall which may be expected, but evidently the longer the period over which observations have extended the nearer that end will be attained. It is sometimes assumed that the lowest annual rainfall likely to be expected in a long period of years is 80 per cent of the average annual rainfall for the same period. Or, it is sometimes assumed that the average rainfall for the lowest two or three consecutive years will be 80 per cent of the average for the entire period, and that the year of minimum rainfall may be expected to yield two thirds of the annual average precipitation. Such features will necessarily vary with the location of the district considered. Conclusions which may be true for the New England or northern Atlantic States probably will not hold for the south Atlantic and Gulf States. Data for such conclusions must be obtained from the rainfall of the locality considered. Table VI exhibits the comparative monthly rainfall which J. T. Fanning suggests may be used approximately for the average Atlantic coast districts.

TABLE VI.

+----------+----------+----------+----------+ | | Mean | | Probable | | | Monthly | Respective | Depth in | | | Rainfall, | Ratios. | Inches of | | | Inches. | | Actual | | | | | Rainfall. | +----------+----------+----------+----------+ | January | 4 × 1.65 = 6.6 | | February | 4 × 1.50 = 6.0 | | March | 4 × 1.65 = 6.6 | | April | 4 × 1.45 = 5.8 | | May | 4 × .85 = 3.4 | | June | 4 × .75 = 3.0 | | July | 4 × .35 = 1.4 | | August | 4 × .25 = 1.0 | | September | 4 × .30 = 1.2 | | October | 4 × .45 = 1.8 | | November | 4 × 1.20 = 4.8 | | December | 4 × 1.60 = 6.4 | +----------+----------+

If the average monthly rainfall throughout the year were one inch, the values of the ratios would show the actual monthly precipitation. In general the table would be used by dividing the total yearly rainfall by 12, and then multiplying that monthly average by the proper ratio taken from the table opposite the month required. Such tables should only be used for approximate purposes and when actual rainfall records are not available for the district considered.

=167. Available Portion of Rainfall or Run-off of Watersheds.=—If the public water-supply is to be drawn from a stream where the desired rainfall records exist, it is necessary to know what portion of the rainfall, either in the driest or in other years, may be available. This is one of the departments of the hydraulics of streams for which much data yet remain to be secured. The watersheds or areas drained by some streams, like the Sudbury River of the Boston, and the Croton of the New York water-supply, have, however, been studied with sufficient care to give reliable data. The amount of water flowing in a stream from any watershed for a given period, as a year, is called the annual “run-off” of the watershed, and it is usually expressed as a certain percentage of

the total rainfall on the area drained. For certain purposes it is sometimes more convenient to express the run-off from the watershed as the number of cubic feet of water per second per square mile of area. Table VII, taken from Turneaure and Russell, exhibits run-off data for a considerable number of streams in connection with both average and minimum rainfalls.

TABLE VII.

The information to be drawn from this table is sufficient to give clear and general relations between the recorded precipitation and run-off. The percentage of run-off is seen to vary quite widely, but as a rule it is materially less for the year of minimum flow than for the average year. That feature of the table is an expression of the general law, other things being equal, that the smaller the precipitation the less will be the percentage of run-off. A number of influences act to produce that result. During a year of great precipitation the earth is more nearly saturated the greater part of the time, and hence when rain falls less of it will percolate into the ground and more of it will run off. Again, if the ground is absolutely dry, a certain amount of rain would have to fall before any run-off would take place. The area and shape of a watershed will also affect to some extent the flow of the stream which drains it. A larger run-off would reasonably be expected from a long narrow watershed than from one more nearly circular in outline. The greater the massing of the watershed, so to speak, the more opportunity there is for the water to be held by the ground and the less would be the run-off.

TABLE VIII.

AVERAGE YIELD OF SUDBURY WATERSHED, 1875-1899, INCLUSIVE, VARIOUSLY EXPRESSED.

(Area of watershed, 75.2 square miles.) ---------+--------------------+------------------------------ | Per Square Mile. | Rainfall. =168. Run-off of Sudbury Watershed.=—Table VIII has been given by Mr. Charles W. Sherman, as representing the average yield of the Sudbury watershed for the period 1875 to 1899, inclusive, expressed in several different ways. The average rainfall was 45.83 inches, and the percentage which represents the run-off is 49.1 per cent of the total. The average monthly run-off varies from .305 cubic foot (for July) to 4.489 cubic feet (for March) per second per square mile. As a general rule it may be stated that the average run-off from the drainage areas of New England streams amounts very closely to 1,000,000 gallons per square mile per day. The area of the Sudbury watershed is 75.2 square miles, with 6.5 per cent of that total area occupied by the surface of lakes or reservoirs. As will presently be seen, the amount of exposed water surface in any watershed has an appreciable influence upon its

run-off.

=169. Run-off of Croton Watershed.=—The total area of the Croton watershed, from which New York City draws its supply, i.e., the area up-stream from the new Croton Dam, is 360.4 square miles, of which 16.1 square miles, or 4.47 per cent, of its total area is water surface. Mr. John R. Freeman found in the investigations covered by his report to the comptroller of the city of New York in 1900 that the average annual rainfall on that area for the thirty-two years beginning 1868 and ending 1899 was 48.07 inches, and that the average run-off for the same period was 47.7 per cent of the total average rainfall, equivalent to a depth of 22.93 inches.

[Illustration: Aqueducts near Jerome Park Reservoir, New York City.]

Table IX gives the main elements of the rainfall and run-off for the Croton watershed during the thirty-two year period, for the averages just given.

TABLE IX.

RAINFALL ON CROTON WATERSHED IN TOTAL INCHES—1868-1898. NATURAL FLOW OF CROTON RIVER AT OLD CROTON DAM, IN EQUIVALENT INCHES. PERCENTAGE OF RUN-OFF TO RAINFALL FOR EACH YEAR.

----------+---------+---------+---------- Year. | Total | Total | |Rainfall.| Run-off.| Per Cent. ----------+---------+---------+---------- 1868 | 50.33 | 33.33 | 66.22 1869 | 48.36 | 23.61 | 48.82 1870 | 44.63 | 19.20 | 43.02 1871 | 48.94 | 19.46 | 39.76 1872 | 40.74 | 16.92 | 41.53 1873 | 43.87 | 25.02 | 57.03 1874 | 42.37 | 25.10 | 59.24 1875 | 43.66 | 24.77 | 56.73 1876 | 40.68 | 21.09 | 51.84 1877 | 48.23 | 20.22 | 41.92 1878 | 55.70 | 27.17 | 48.78 1879 | 47.04 | 19.65 | 41.77 1880 | 36.92 | 12.63 | 34.21 1881 | 46.69 | 19.25 | 41.23 1882 | 52.35 | 24.28 | 46.38 1883 | 42.70 | 13.33 | 31.22 1884 | 51.28 | 24.08 | 46.96 1885 | 43.67 | 17.71 | 40.55 1886 | 47.74 | 20.10 | 42.10 1887 | 57.29 | 26.61 | 46.45 1888 | 60.69 | 35.27 | 58.12 1889 | 55.70 | 31.39 | 56.36 1890 | 54.05 | 25.95 | 48.01 1891 | 47.20 | 23.48 | 49.75 1892 | 44.28 | 17.68 | 39.93 1893 | 54.87 | 29.05 | 52.94 1894 | 47.33 | 20.56 | 43.44 1895 | 40.58 | 15.95 | 39.31 1896 | 45.85 | 23.26 | 50.73 1897 | 53.12 | 25.59 | 48.17 1898 | 57.40 | 29.72 | 51.77 1899 | 44.67 | 22.28 | 49.88 Average for| 48.07 | 22.93 | 47.70 32 years. | | | ----------+---------+---------+----------

The table shows that the least annual rainfall was 36.92 inches for 1880, and that the run-off represented a depth of 12.63 inches only, or 34.21 per cent of the total annual precipitation. As a rule the same feature of a low percentage of run-off will be found belonging to the years of low rainfall, although there are many irregularities in the results. On the other hand, the high percentages of run-off are for the years 1868, 1888, and 1889, and they will generally be found belonging to years of relatively great precipitation. A low percentage of run-off will also be lower if the year to which it belongs follows a dry year or a dry cycle of two or three years. Similarly the high percentages of run-off will, as a rule, be higher if they follow years of high precipitation; that is, if they belong to a cycle of relatively great rainfall.

=170. Evaporation from Reservoirs.=—If it is contemplated to build reservoirs on a watershed the capacity of which is being estimated on the basis of either the driest year or the driest two- or three year cycle, it is necessary to make a deduction from the rainfall for the evaporation which will take place from the surface of the proposed reservoir. In order that that deduction may be made as a proper allowance for added water surface in a drainage area, it is necessary that the amount of evaporation be determined for the district considered. The rate of evaporation is dependent upon the area of water surface, upon the wind, and upon the temperature both of the water and air above it. Numerous evaporation observations have been made both in this and other countries, and extensive evaporation tables have been prepared by the Weather Bureau, from which a reasonable estimate of the monthly evaporation for all months in the year may be made for almost any point in the United States. Particularly available observations have been made by Mr. Desmond Fitzgerald of Boston on the Chestnut Hill reservoirs of the Boston Water-supply, and by Mr. Emil Kuichling, engineer of the Rochester Water-works, on the Mount Hope reservoir of the Rochester supply. Table X exhibits the results of the observations of both these civil engineers.

[Illustration: Aqueduct Division Wall of Jerome Park Reservoir, New York City.]

As would be anticipated, the period from May to September, both inclusive, shows by far the greatest evaporation of the whole year, while December, January, and February are the months of least evaporation. The total annual evaporation at Boston was 39.2 inches and 34.54 inches at Rochester.

TABLE X.

MEAN MONTHLY EVAPORATIONS. ----------+------------------------+------------------------ | | | Chestnut Hill Reservoir,| Mount Hope Reservoir, Month. | Boston, Mass. | Rochester, N. Y. | | ----------+------------+------------+------------+------------ | | Per Cent | | Per Cent |Evaporation,| of Yearly |Evaporation,| of Yearly | Inches. |Evaporation.| Inches. |Evaporation. ----------+------------+------------+------------+------------ January | 0.96 | 2.4 | 0.52 | 1.5 February | 1.05 | 2.7 | 0.54 | 1.6 March | 1.70 | 4.3 | 1.33 | 3.9 April | 2.97 | 7.6 | 2.62 | 7.6 May | 4.46 | 11.4 | 3.93 | 11.4 June | 5.54 | 14.2 | 4.94 | 14.3 July | 5.98 | 15.2 | 5.47 | 15.8 August | 5.50 | 14.0 | 5.30 | 15.4 September | 4.12 | 10.4 | 4.15 | 12.0 October | 3.16 | 8.1 | 3.16 | 9.1 November | 2.25 | 5.7 | 1.45 | 4.2 December | 1.51 | 3.9 | 1.13 | 3.2 +------------+------------+------------+------------ Total for year | 39.20 | | 34.54 | +------------+------------+------------+------------ Mean temperature| 48°.6 | 47°.8 ----------+------------------------+------------------------

A reference to data of the Weather Bureau will show that annual evaporation as high as 100 inches, or even more, may be expected on the plateaux of Arizona and New Mexico. Other portions of the arid country in the western part of the United States will indicate annual evaporations running anywhere from 50 to 90 inches per year, while on the north Pacific coast it will fall as low as 18 to 40 inches.

=171. Evaporation from the Earth's Surface.=—Data are lacking for anything like a reasonably accurate estimate of evaporation from the earth's surface. It is well known that the loss of water from that source is considerable in soils like those of swamps, particularly when exposed to the warm sun, but no reliable estimate can be obtained for the exact amount. Nor is this necessary for the usual water-supply problems, since it is included in the difference between the total rainfall of any district and the observed run-off in the streams. Indeed evaporation from reservoirs is similarly included for reservoirs existing when the run-off observations are made.

CHAPTER XVI.

=172. Application of Fitzgerald's Results to the Croton Watershed.=—The evaporation data determined by Messrs. Fitzgerald and Kuichling are sufficient for all ordinary purposes in the North Atlantic States. In the discussion of the capacity of the Croton watershed Mr. Fitzgerald's results will be taken, as the conditions of the Croton watershed in respect to temperature and atmosphere are affected by the proximity to the ocean, and other features of the case make it more nearly like the Metropolitan drainage area near Boston than the more elevated inland district near Rochester.

If the monthly amounts of evaporation be taken from the preceding table, and if it further be observed that a volume of water 1 square mile in area and 1 inch thick contains 17,377,536 gallons, the following table (Table XI) of amounts of evaporation from the reservoirs in the Croton watershed, including the new Croton Lake, will result, since the total area of water surface of all these reservoirs is 16.1 square miles.

TABLE XI.

Jan. 0.96 × 16.1 × 17,377,536 = 268,600,000 gallons. Feb. 1.05 × ” × ” = 293,800,000 ” Mar. 1.70 × ” × ” = 475,700,000 ” April 2.97 × ” × ” = 831,000,000 ” May 4.46 × ” × ” = 1,247,900,000 ” June 5.54 × ” × ” = 1,550,100,000 ” July 5.98 × ” × ” = 1,673,200,000 ” Aug. 5.50 × ” × ” = 1,538,900,000 ” Sept. 4.12 × ” × ” = 1,152,800,000 ” Oct. 3.16 × ” × ” = 884,200,000 ” Nov. 2.25 × ” × ” = 629,600,000 ” Dec. 1.51 × ” × ” = 422,500,000 ” ----- ---------- 39.20 Total = 10,968,300,000 ”

It will be seen from this table that the total annual evaporation from all the reservoir surfaces of the Croton watershed, as it will exist when the new Croton Lake is completed, will be nearly 11,000,000,000 gallons, enough to supply the boroughs of Bronx and Manhattan at the present rate of consumption for about forty days.

=173. The Capacity of the Croton Watershed.=—The use of the preceding figures and numbers can be well illustrated by considering the capacity of the Croton watershed in its relations to the present water needs of the boroughs of Bronx and Manhattan which that watershed is designed to supply. The total area of the Croton watershed is 360.4 square miles, of which 16.1 square miles, as has already been observed, is water surface. As a matter of fact the run-off observations from that watershed have been maintained or computed for the thirty-two-year period from 1868 to 1899, inclusive, covering the evaporation from the reservoirs and lake surfaces as they have existed during that period. The later observations, therefore, include the effects of evaporation from the more lately constructed reservoirs, but none of these data cover evaporation from the entire surface of the new Croton Lake, whose excess over that of the old reservoir is nearly one third of the total water surface of the entire shed. As a margin of safety and for the purpose of simplification, separate allowance will be made for the evaporation from all the reservoir and lake surfaces of the entire watershed as it will exist on the completion of the new Croton Lake, as a deduction from the run-off. The

preceding table (Table XI) exhibits those deductions for evaporation as they will be made in the next table.

In Table IX the year 1880 yields the lowest run-off of the entire thirty-two-year period. The total precipitation was 36.92 inches, and only 34.21 per cent of it was available as run-off. The first column in Table XII gives the amount of monthly rainfall for the entire year, the sum of which aggregates 36.92 inches. Each of these monthly quantities multiplied by .3421 will give the amount of rainfall available for run-off, and the latter quantity multiplied by the number of square miles in the watershed (360.4) will show the total depth of available water concentrated upon a single square mile. If the latter quantity be multiplied by 17,378,000, the total number of gallons available for the entire month will result, from which must be subtracted the evaporation for the same month. Carrying out these operations for each month in the year, the monthly available quantities for water-supply will be found, as shown in the last column.

TABLE XII.

(Jan. 3.43 × .3421 = 1.173) × 360.4 × 17,378,000 - 268,600,000 = 7,077,700,000 (Feb. 3.40 × ” = 1.163) × ” × ” - 293,800,000 = 6,989,900,000 (Mar. 3.90 × ” = 1.334) × ” × ” - 475,700,000 = 7,879,000,000 (April 3.57 × ” = 1.221) × ” × ” - 831,000,000 = 6,816,000,000 (May 1.04 × ” = .356) × ” × ” - 1,247,900,000 = 982,000,000 (June 1.40 × ” = .479) × ” × ” - 1,550,100,000 = 1,449,800,000 (July 5.86 × ” = 2.005) × ” × ” - 1,673,200,000 = 10,890,000,000 (Aug. 4.16 × ” = 1.423) × ” × ” - 1,538,900,000 = 7,373,100,000 (Sept. 2.42 × ” = .828) × ” × ” - 1,152,800,000 = 4,032,900,000 (Oct. 2.83 × ” = .968) × ” × ” - 884,200,000 = 5,178,500,000 (Nov. 2.32 × ” = .794) × ” × ” - 629,600,000 = 4,343,100,000 (Dec. 2.59 × ” = .886) × ” × ” - 422,500,000 = 5,126,300,000 ----- 36.92

The sum of the twelve monthly available quantities will give the total number of gallons per year applicable to meeting the water demands of the boroughs of Bronx and Manhattan.

=174. Necessary Storage for New York Supply to Compensate for Deficiency.=—At the present time the average daily consumption per inhabitant of those two boroughs is 115 gallons, and if the total population be taken at 2,200,000, the total daily consumption will be 2,200,000 × 115 = 253,000,000 gallons. If the latter quantity be multiplied by 30.5, the latter being taken as the average number of days in the month throughout the year, the average monthly draft of water for the two boroughs in question will be 7,716,500,000 gallons. The subtraction of the latter quantity from the monthly results in the preceding table will exhibit a deficiency which must be met by storage or a surplus available for storage. Table XIII exhibits the twelve monthly differences of that character.

TABLE XIII.

7,077,700,000 — 7,716,500,000 = - 638,800,000 6,989,900,000 — ” = - 726,600,000 7,879,000,000 — ” = + 162,500,000 6,816,000,000 — ” = - 900,500,000 982,000,000 — ” = - 6,734,500,000 1,449,800,000 — ” = - 6,266,700,000 10,890,000,000 — ” = +3,173,500,000 7,373,100,000 — ” = - 343,400,000 4,032,900,000 — ” = - 3,683,600,000 5,178,500,000 — ” = - 2,538,000,000 4,343,100,000 — ” = - 3,373,400,000 5,126,300,000 — ” = - 2,590,200,000 ---------- ---------- -27,795,700,000 +3,336,000,000 + 3,336,000,000 ---------- -24,459,700,000

It is seen from this table that the total monthly deficiencies aggregate 27,795,700,000 gallons and that there are only two months in which the run-off exceeds the consumption, the surplus for those two months being only 3,336,000,000 gallons. The total deficiency for the year is therefore 24,459,700,000 gallons. Dividing the latter quantity by the average daily draft of 253,000,000 gallons, there will result a period of 97 days, or more than one quarter of a year, during which the minimum annual rainfall would fail to supply any water to the city at all. These results show that in case of a low rainfall year, like that of 1880, the precipitation upon the Croton watershed would supply sufficient water for the boroughs of Bronx and Manhattan at the present rate of consumption for three fourths of the year only. A distressingly serious water famine would result unless the year were begun by sufficient available storage in the reservoirs of the basin at least equal to 24,459,700,000 gallons. Should such a low rainfall year or one nearly approaching it be one of a two- or three-year low rainfall cycle, such a reserve storage would be impossible and the resulting conditions would be most serious for the city. If an average year, for which the total rainfall would be about 48 inches preceded such a year of low rainfall, the conditions would be less serious. The figures would stand as follows:

Total run-off = 17,377,536 × 360.4 × 22.93 - 17,377,536 × 16.1 × 39.2 = 132,640,000,000 gallons.

Total annual consumption = 92,345,000,000 ” ---------- Available for storage = 40,295,000,000 ” Deficiency = 24,459,700,000 ” ---------- Surplus = 15,835,300,000 ”

The average year would, therefore, yield enough run-off water if stored to more than make up the deficiency of the least rainfall year by nearly 16,000,000,000 gallons. In order to secure the desired volume it would therefore be necessary to have storage capacity at least equal to 24,459,700,000 gallons; indeed, in order to meet all the exigencies of a public water-supply it would be necessary to have far more than that amount. As a matter of fact there are in the Croton watershed seven artificial reservoirs with a total storage capacity of nearly 41,000,000,000 gallons, besides a number of small ponds in addition to the new Croton Lake which with water surface at the masonry crest of the dam has a total additional storage capacity of 23,700,000,000 gallons. The storage capacity of the new Croton Lake may be increased by the use of flash-boards 4 feet high placed along its crest, so that with its water surface at grade 200 its total capacity will be increased to 26,500,000,000 gallons. After the new Croton reservoir is in use the total storage capacity of all the reservoirs and ponds in the Croton watershed will be raised to 70,245,000,000 gallons, which can be further augmented by the Jerome Park reservoir when completed by an amount equal to 1,900,000,000 gallons. This is equivalent, at the present rate of consumption, to a storage supply for 285 days for the boroughs of Manhattan and the Bronx.

=175. No Exact Rule for Storage Capacity.=—This question of the amount of storage capacity to be provided in connection with public water-supplies is one which cannot be reduced to an exact rule. Obviously if the continuous flow afforded from any source is always greater per day than any draft that can ever be made upon it, no storage-reservoirs at all would be needed, although they might be necessary for the purpose of sedimentation. On the other hand, as in the case of New York City, if the demand upon the supply has reached its capacity or exceeded it for low rainfall years, it may be necessary to provide storage capacity sufficient to collect all the run-off of the watershed. The civil engineer must from his experience and from the data before him determine what capacity between those limits is to be secured. When the question of volume or capacity of storage is settled the mode of distribution of that volume or capacity in reservoirs is to be determined, and that affects to some extent the potability of the water. If there is a large area of shallow storage, the vegetable matter of the soil may affect the water in a number of ways. Again, it is advisable in this connection to consider certain reservoir effects as to color and contained organic matter in general.

=176. The Color of Water.=—The potability[7] of water collected from any watershed is materially affected by its color. Although iron may produce a brownish tinge, by far the greater amount of color is produced by dissolved vegetable matter. Repeated examinations of colored water have shown that discoloration is in many cases at least a measure of the vegetable matter contained in it. While this may not indicate that the water is materially unwholesome, it shows conclusively the existence of conditions which are usually productive of minute lower forms of vegetation from which both bad taste and odors are likely to arise.

[7] What is generally known as the “Michigan standard of the purity of drinking-water,” as specified by the Michigan State Laboratory of Hygiene, is here given:

“1. The total residue should not exceed 500 parts per million. “2. The inorganic residue may constitute the total residue. “3. The smaller amount of organic residue the better the water. “4. The amount of earthy bases should not exceed 200 parts per million. “5. The amount of sodium chloride should not exceed 20 parts per million (i.e., ‘chlorine’ 12.1 parts per million). “6. The amount of sulphates should not exceed 100 parts per million. “7. The organic matter in 1,000,000 parts of the water should not reduce more than 8 parts of potassium permanganate (i.e., ‘required oxygen’ 2.2 parts per million). “8. The amount of free ammonia should not exceed 0.05 part per million. “9. The amount of albuminoid ammonia should not exceed 0.15 part per million. “10. The amount of nitric acid should not exceed 3.5 parts per million (i.e., ‘N as nitrate’ .9 part per million). “11. The best water contains no nitrous acid, and any water which contains this substance in quantity sufficient to be estimated should not be regarded as a safe drinking-water. “12. The water must contain no toxicogenic germs as demonstrated by tests upon animals.

“The water must be clear and transparent, free from smell, and without either alkaline or acid taste, and not above 5 French standard of hardness.”

This standard is too high to be attained ordinarily in natural waters.

There are two periods in the year of maximum intensity of color, one occurring in June and the other in November. The former is due to the abundant drainage of peaty or other excessively vegetable soils from the spring rains. After June the sun bleaches the water to a material extent until the autumn, when the dying vegetation imparts more or less coloring to the water falling upon it. This last agency produces its maximum effect in the month of November.

There are various arbitrary scales employed by which colors may be measured and discolored waters compared. Among others, dilute solutions of platinum and cobalt are used, in which the relative proportions of those substances are varied so as to resemble

closely the colors of the water. The amount of platinum used is a measure of the color, one unit of which corresponds to one part of the metal in 10,000 parts of water. Again, the depth at which a platinum wire 1 mm. (.039 inch) in diameter and 1 inch long can be seen in the water is also taken as a measure of the color, the amount of the latter being inversely as the depth. This method has found extended and satisfactory use in connection with the Metropolitan Water-supply of Boston, the Cochituate water having a degree of color represented by .25 to .30, while the Sudbury water has somewhat more than twice as much. The Cochituate water is practically colorless.

The origin of the color of water is chiefly the swamps which drain into the water-supply, or the vegetation remaining upon a new reservoir site when the surface soil has not been removed before the filling of the reservoir. The drainage of swamps should not, as a rule, be permitted to flow into a public water-supply, as it is naturally heavily charged with vegetable matter and is correspondingly discolored. This matter, like many others connected with the sanitation of potable public waters, has been most carefully investigated by the State Board of Health of Massachusetts in connection with the Boston water-supply. Its work has shown the strong advisability of diverting the drainage of large swamps from a public supply as carrying too much vegetable matter even when highly diluted by clear water conforming to desirable sanitary standards.

=177. Stripping Reservoir Sites.=—The question of stripping or cleaning reservoir sites of soil is also one which has been carefully studied by the Massachusetts State Board of Health. As a consequence large amounts of money have been expended by the city of Boston in stripping the soil from reservoir sites to the average depth in some cases of 9 inches for wooded land and 12½ inches for meadow land. This was done in the case of the Nashua River reservoir having a superficial area of 6.56 square miles at a cost of nearly $2,910,000, or about $700 per acre. It has been found that the beneficial effect of this stripping is fully secured if the black loam in which vegetation flourishes is removed.

[Illustration: Wachusetts Reservoir, showing Stripping of Soil.]

This stripping of soil is indicative of the great care taken to secure a high quality of water for the city of Boston, but it is not done in the Croton watershed of the New York supply. It cannot be doubted that the quality of the Croton supply would have been sensibly enhanced by a similar treatment of its reservoir sites. Mr. F. B. Stearns, chief engineer of the Metropolitan Water-supply of Boston, states that in some cases the effects of filling reservoirs without removing the soil and vegetable matter have “continued for twenty years or more without apparent diminution.” On the other hand, water discolored by vegetable matter becomes bleached to some extent at least by standing in reservoirs whose sites have been stripped of soil.

=178. Average Depth of Reservoirs should be as Great as Practicable.=—In the selection of reservoir locations those are preferable where the average depths will be greatest and where shallow margins are reduced to a minimum. It may sometimes be necessary to excavate marginal portions which would otherwise be shallow with a full reservoir. There should be as little water as possible of a less low-water depth than 10 or 12 feet, otherwise there may be a tendency to aquatic vegetable growth. The following table exhibits the areas, average depths, capacity, and other features of a number of prominent storage-reservoirs.

COMPARATIVE TABLE OF AREAS, DEPTHS, AND CAPACITIES OF STORAGE RESERVOIRS WITH HEIGHTS AND LENGTHS OF DAMS.

=179. Overturn of Contents of Reservoirs Due to Seasonal Changes of Temperature.=—It will be noticed that the average depth is less than about 20 feet in few cases only. If the water is deep, its mean temperature throughout the year will be lower than if

shallow. During the warmer portion of the year the upper layers of the water are obviously of a higher temperature than the lower portions, since the latter receive much less immediate effect from the sun's rays. As the upper portions of the water are of higher temperature, they are also lighter and hence remain at or near the top. For the same reason the water at the bottom of the reservoir remains there throughout the warm season and until the cool weather of the autumn begins. The top layers of water then continue to fall in temperature until it is lower than that of the water at the bottom, when the surface-water becomes the heaviest and sinks. It displaces subsurface water lighter than itself, the latter coming to the surface to be cooled in turn.

This operation produces a complete overturning of the entire reservoir volume as the late autumn or early winter approaches. It thus brings to the surface-water which has been lying at the bottom of the reservoir all summer in contact with what vegetable matter may have been there. The depleted oxygen of the bottom water is thus replenished with a corresponding betterment of condition. It is the great sanitary effort of nature to improve the quality of stored water entrusted to its care, and it continues until the surface is cooled to a temperature perhaps lower than that of the greatest density of water.

Another great turn-over in the water of a lake or reservoir covered with ice during the winter occurs in the spring. When the ice melts, the resulting water rises a little in temperature until it reaches possibly its greatest density at 39°.2 Fahr., and then sinks, displacing subsurface water. This goes on until all the ice is melted and until all water cooled by it, near the surface, below 39°.2 Fahr. has been raised to that temperature. The period of summer stagnation then follows.

=180. The Construction of Reservoirs.=—The natural topography and sometimes the geology of the locality determines the location of the reservoir. The first requirement obviously is tightness. If for any reason whatever, such as leaky banks or bottom, porous subsurface material, or for any other defect, the water cannot be retained in the reservoir, it is useless. Some very perplexing questions in this connection have arisen. Indeed reservoirs have been completed only to be found incapable of holding their contents. Such results are evidently not creditable to the engineers who are responsible for them, and they should be avoided.

[Illustration: YARROW RESERVOIR, LIVERPOOL WATER-SUPPLY]

[Illustration: SAN LEANDRO DAM, SAN FRANCISCO WATER-WORKS]

[Illustration: TITICUS DAM, NEW YORK WATER-SUPPLY]

In order that the bottom of the reservoir may be water-tight it must be so well supported by firm underlying material that it will not be injured by the weight of water above it, which in artificial reservoirs may reach 30 to 100 feet or more in depth. The subsurface material at the site of any proposed structure of this character must, therefore, be carefully examined so as to avoid all porous material, crevasses in rocks, or other open places where water might escape. Objectionable material may frequently be removed and replaced with that which is more suitable, and rock crevices and other open places may sometimes be filled with concrete and made satisfactory. Whatever may be the conditions existing, the finished bottom of the reservoir should be placed only on well-compacted, firm, unyielding material.

The character of the reservoir bottom will depend somewhat upon the cost of suitable material of which to construct it. If a bottom of natural earth cannot be used, a pavement of stone, brick, or concrete may be employed from 8 inches to a foot or a foot and a half in thickness. The reservoir banks must be placed upon carefully prepared foundations, sometimes with masonry core-walls. They are frequently composed of clayey and gravelly material mixed in proper proportions and called puddle, although that term is more generally applied to a mixture of clay and gravel designed to form a truly impervious wall in the centre of the reservoir embankment. Some engineers require the core-wall, as it is called, to be constructed of masonry, with the earth or gravelly material carried up each side of this wall in layers 6 to 9 inches thick, well moistened and each layer thoroughly rolled with a grooved roller, or treated in some equivalent manner in order that the whole mass may not be in strata but essentially continuous and as nearly impervious as possible. The masonry core-wall should be founded on bed-rock or its equivalent. Its thickness will depend upon the height of the embankment. If the latter is not more than 20 or 25 feet high, the core-wall need not be more than 4 to 6 feet thick, but if the embankment reaches a height of 75 feet or even 100 feet, it must be made 15 to 20 feet thick, or possibly more, at the base. Its top should be not less than 4 or 6 feet thick, imbedded in the earth and carried well above the highest surface of water in the reservoir.

The thickness of the clay puddle-wall employed as the central core of the reservoir embankment is usually made much thicker than that of masonry. As a rough rule it may be made twice as thick as the masonry core at the deepest point and not less than about 6 feet at the top. The thickness of the puddle core is sometimes varied to meet the requirements of the natural material in which it is embedded at different depths.

Frequently, when embankments are under about 20 feet high, the core-walls may be omitted, excavation having been made at the base of the embankment down to rock or other impervious material, and if the entire bank is carried up with well-selected and puddled material.

The interior slopes of reservoir embankments are usually covered with roughly dressed stone pavement 12 to 18 inches thick, laid upon a broken stone foundation 8 to 12 inches thick, for a protection against the wash of waves, the pavement in any case being placed upon the bank slope after having been thoroughly and firmly compacted. The sloping and bottom pavements, of whatever material they may be composed, should be made continuous with each other so as to offer no escape for the water. In some cases where it has been found difficult to make the interior surfaces of reservoirs water-tight, asphalt or other similar water-tight layers have been used with excellent results.

The care necessary to be exercised in the construction of storage or other reservoirs when earth dams or embankments are used can better be appreciated when it is realized that almost all such banks, even when properly provided with masonry or clay-puddle core-walls, are saturated with water, even on the down-stream side, at least throughout their lower portions. A board of engineers appointed by the commissioners of the Croton Aqueduct in the summer of 1901 made a large number of examinations in the earth embankments in the Croton watershed, and found that with scarcely an exception those embankments were saturated throughout the lower portions of their masses, although in every case a masonry core-wall had been built. The results of those investigations showed that the water had percolated through the earth portion of the embankments and even through the core-walls, which had been carried down to bed-rock. This induced saturation, more or less, of the material on the down-stream slopes of the embankments. When material is thus filled with water, unless it is suitably selected, it is apt to become soft and unstable, so that any superincumbent weight resting upon it might produce failure. The fact that such embankments may become saturated with water fixes limits to their heights, since the surface of saturation in the interior of the bank has generally a flatter slope than that of the exterior surface. The height of the embankment therefore should be such that the exterior slope cannot cut into the saturated material at its foot, at least to any great extent. From what precedes it is evident that the height of an earth embankment will depend largely upon the slope of the exterior surface. This slope is made 1 vertical to 2, 2½, or 3 horizontal. The more gradual slope is sometimes preferable. It is advisable also to introduce terraces and to encourage the growth of sod so as to protect the surface from wash. The inner paved slope may be as steep as 1 vertical to 1½ or 2 horizontal.

[Illustration: AMAWALK DAM.—RESERVOIR A.

Earth Dams in Croton Watershed, showing Slopes of Saturation.]

=181. Gate-houses, and Pipe-lines in Embankments.=—It is necessary to construct the requisite pipe-lines and conduits leading from the storage-reservoirs to the points of consumption, and sometimes such lines bring the water to the reservoir. Wherever such pipes-line or conduits either enter or leave a reservoir gates and valves must be provided so as properly to control the admission and outflow of the water. These gate-houses, as they are called, because they contain the gates or valves and such other appurtenances or details as are requisite for operation and maintenance, are usually built of substantial masonry. They are the special outward features of every reservoir construction, and their architecture should be characteristic and suitable to the functions which they perform. Where the pipes are carried through embankments it is necessary to use special precautions to prevent the water from flowing along their exterior surfaces. Many reservoirs have been constructed under defective design in this respect, and their embankments have failed. Frequently small masonry walls are built around the pipes and imbedded in the bank, so as to form stops for any initial streams of water that might find their way along the pipe. In short, every care and resource known to the civil engineer must be employed in reservoir construction to make its bottom and its banks proof against leakage and to secure permanence and stability in every feature.

=182. High Masonry Dams.=—The greatest depths of water impounded in reservoirs are found usually where it is necessary to construct a high dam across the course of a river, as at the new Croton dam. In such cases it is not uncommon to require a dam over 75 to 100 feet high above the original bed of the river, which is usually constructed of masonry with foundations carried down to bed-rock in order to secure suitable stability and prevent flow or leakage beneath the structure. It is necessary to secure that result not only along the foundation-bed of the dam, but around its ends, and special care is taken in those portions of the work.

The new Croton dam is the highest masonry structure of its class yet built. The crest of its masonry overflow-weir is 149 feet above the original river-bed, with the extreme top of the masonry work of the remaining portion of the dam carried 14 feet higher. A depth of earth and rock excavation of 131 feet below the river-bed was necessary in order to secure a suitable foundation on bed-rock. The total maximum height, therefore, of the new Croton dam, from the lowest foundation-point to the extreme top, is 294 feet, and the depth of water at the up-stream face of the dam will be 136 feet when the overflow is just beginning, or 140 feet if 4 feet additional head be secured by the use of flash-boards. In the prosecution of this class of work it is necessary not only to reach bed-rock, but to remove all soft portions of it down to sound hard material, to clean out all crevices and fissures of sensible size, refilling them with hydraulic cement mortar or concrete, and to shape the exposed rock surfaces so as to make them at least approximately normal to the resultant loads upon them, to secure a complete and as nearly as possible water-tight bond with the superimposed masonry. If any streams or other small watercourses should be encountered, they must either be stopped or led off where they will not affect the work, or, as is sometimes done, the water issuing from them may be carried safely through the masonry mass in small pipes. The object is to keep as much water out of the foundation-bed as possible, so as to eliminate upward pressure underneath the dam caused by the head of water in the subsequently full reservoir. It is a question how much dependence can be placed upon the exclusion of water from the foundation-bed. In the best class of work undoubtedly the bond can be good enough to exclude more or less water, but it is probably only safe and prudent so to design the dam as to be stable even though water be not fully excluded.

[Illustration: Cross-section of New Croton Dam.]

The stability of the masonry dam must be secured both for the reservoir full and empty. With a full reservoir the horizontal pressure of water on the up-stream face tends to overturn the dam down-stream. When the water is entirely withdrawn the pressure under the up-stream edge of the foundation becomes much greater, so that safety and stability under both extreme conditions must be assured. There are a number of systems of computation to which engineers resort in order to secure a design which shall certainly be stable under all conditions. That which is commonly employed in this country is based upon two fundamental propositions, under one of which the pressure at any point in the entire masonry mass must not exceed a certain safe amount per square foot, while the other is of a more technical character, requiring that the centre of pressure shall, in every horizontal plane of the dam, approach nowhere nearer than one third the horizontal thickness of the masonry to one edge of it. A further condition is also prescribed which prevents any portion of the dam from slipping or sliding over that below it. As a matter of fact when the first two conditions are assured the third is usually fulfilled concurrently. Obviously there will be great advantage accruing to a dam if the entire mass of masonry is essentially monolithic. In order that that may be the case either concrete or rubble is usually employed for the great mass of the masonry structure, the exterior surfaces frequently being composed of a shell of cut-stone, so as to provide a neat and tasteful finish. This exterior skin or layer of cut masonry need not average more than 1½ to 2½ feet thick.

The pressures prescribed for safety in the construction of masonry dams vary from about 16,000 to 28,000 or 30,000 pounds per square foot. Sometimes, as in the masonry dams found in the Croton watershed, limits of 16,000 to 20,000 pounds per square foot are prescribed for the upper portions of the dams and a gradually increasing pressure up to 30,000 pounds per square foot in passing downward to the foundation-bed. There are reasons of a purely technical character why the prescribed safe working pressure must be taken less on the down-stream or front side of the dam than on the up-stream or rear face.

The section of a masonry dam designed under the conditions outlined will secure stability through the weight of the structure alone, hence it is called a gravity section. In some cases the rock bed and sides of a ravine in which the stream must be dammed will permit a curved structure to be built, the curvature being so placed as to be convex up-stream or against the water pressure. In such a case the dam really becomes a horizontal arch and, if the curvature is sufficiently sharp, it may be designed as an arch horizontally pressed. The cross-section then has much less thickness (and hence less area) than if designed on a straight line so as to produce a gravity section. A number of such dams have been built, and one very remarkable example of its kind is the Bear Valley dam in California; it was built as a part of the irrigation system.

[Illustration: Foundation Masonry of New Croton Dam.]

CHAPTER XVII.

=183. Gravity Supplies.=—When investigation has shown that a sufficient quantity of water may be obtained for a required public supply from any of the sources to which reference has been made, and that a sufficient storage capacity may be provided to meet the exigencies of low rainfall years, it will be evident if the water can be delivered to the points of consumption by gravity, or

whether pumping must be employed, or recourse be made to both agencies.

If the elevation of the source of supply is sufficiently great to permit the water to flow by gravity either to storage-reservoirs or to service-reservoirs and thence to the points of consumption, a proper pipe-line or conduit must be designed to afford a suitable channel. If the topography permits, a conduit may be laid which does not run full, but which has sufficient grade or slope to induce the water to flow in it as if it were an open channel. This is the character of such great closed masonry channels as the new and old Croton aqueducts of the New York water-supply and the Sudbury and Wachusetts aqueducts of the Boston supply. These conduits are of brick masonry backed with concrete carried sometimes on embankments and sometimes through rock tunnels. When they act like open channels a very small slope is employed, 0.7 of a foot per mile being a ruling gradient for the new Croton aqueduct, and 1 foot per mile for the Sudbury. Where these conduits cross depressions and follow approximately the surface, or where they pass under rivers, their construction must be changed so that they will not only run full, but under greater or less pressure, as the case may be.

=184. Masonry Conduits.=—In general the conduits employed to bring water from the watersheds to reservoirs at or near places of consumption may be divided into two classes, masonry and metal, although timber-stave pipes of large diameter are much used in the western portion of the country. The masonry conduits obviously cannot be permitted to run full, meaning under pressure, for the reason that masonry is not adapted to resist the tension which would be created under the head or pressure of water induced in the full pipe. They must rather be so employed as to permit the water to flow with its upper surface exposed to the atmosphere, although masonry conduits are always closed at the top. In other words, they must be permitted to run partially full, the natural grade or slope of the water surface in them inducing the necessary velocity of flow or current. Evidently the velocity in such masonry conduits is comparatively small, seldom exceeding about 3 feet per second. The new and old Croton aqueducts, the Sudbury and Wachusetts aqueducts of the Metropolitan Water-supply of Boston, are excellent types of such conveyors of water. They are sometimes of circular shape, but more frequently of the horseshoe outline for the sides and top, with an inverted arch at the bottom for the purpose of some concentration of flow when a small amount of water is being discharged and for structural reasons.

The interiors of these conduits are either constructed of brick or they may be of concrete or other masonry affording smooth surfaces. In the latest construction Portland-cement concrete or that concrete reinforced with light rods of iron or steel is much used. Bricks, if employed, should be of good quality and laid accurately to the outline desired with about ¼-inch joints, so as to offer as smooth a surface as possible for the water to flow over. In special cases the interiors of these conduits may be finished with a smooth coating of Portland-cement mortar. If conduits are supported on embankments, great care must be exercised in constructing their foundation supports, since any sensible settlement would be likely to form cracks through which much water might easily escape. When carried through tunnels they are frequently made circular in outline. They must occasionally be cleaned, especially in view of the fact that low orders of vegetable growths appear on their sides and so obstruct the free flow of water.

=185. Metal Conduits.=—Metal conduits have been much used within the past fifteen or twenty years. Among the most prominent of these are the Hemlock Lake aqueduct of the Rochester Water-works, and that of the East Jersey Water Company through which the water-supply of the city of Newark, N. J., flows. When these metal conduits or pipes equal 24 to 30 or more inches in diameter they are usually made of steel plates, the latter being of such thickness as is required to resist the pressure acting within them. The riveted sections of these pipes may be of cylindrical shape, each alternate section being sufficiently small in diameter just to enter the other alternate sections of little larger diameter, the interior diameter of the larger sections obviously being equal to the interior diameter of the smaller sections plus twice the thickness of the plate. Each section may also be slightly conical in shape, the larger ends having a diameter just large enough to pass sufficiently over the smaller end of the next section to form a joint. Large cast-iron pipes are also sometimes used to form these metal conduits up to an interior diameter of 48 inches. The selection of the type of conduit within the limits of diameter adapted to both metals is usually made a matter of economy. The interior of the cast-iron pipe is smoother than that of the riveted steel, although this is not a serious matter in deciding upon the type of pipe to be used.

Steel-plate conduits have been manufactured and used up to a diameter of 9 feet. In this case the pipe was used in connection with water-power purposes and with a length of 153 feet only, the plates being ½ inch thick. The steel-plate conduits of the East Jersey Water Company's pipes are as follows:

Diameter. Thickness. Length.

48 inches ¼ inch } 48 ” ■/■■ ” } 21 miles. 48 ” ■ ” } 36 ” ¼ ” 5 ”

The diameters and lengths of the metal pipes or conduits of the Hemlock Lake conduit of the Rochester Water-works are as follows:

36-inch wrought-iron pipe 9.60 miles. 24 ” ” ” 2.96 ” 24 ” cast-iron pipe 15.82 ” ----- Total 28.39 ”

All metal conduits or pipes are carefully coated with a suitable asphalt or tar preparation or varnish applied hot and sometimes baked before being put in place. This is for the purpose of protecting the metal against corrosion. Cast-iron pipes have been used longer and much more extensively than wrought-iron or steel, but an experience extending over thirty to forty years has shown that the latter class of pipes possesses satisfactory durability and may be used to advantage whenever economical considerations may be served.

=186. General Formula for Discharge of Conduits—Chezy’s Formula.=—It is imperative in designing aqueducts of either masonry or metal to determine their discharging capacity, which in general will depend largely upon the slope of channel or head of water and the resistance offered by the bed or interior of the pipe to the flow of water. The resistance of liquid friction is so much more than all others in this class of water-conveyors that it is usually the only one considered. There is a certain formula much used by civil engineers for this purpose; it is known as Chezy’s formula, for the reason that it was first established by the French engineer Antoine Chezy about the year 1775, although it is an open question whether the beginnings of the formula were not made twenty or more years prior to that date. Its demonstration involves the general consideration of the resistance which a liquid meets in flowing over any surface, such as that of the interior of a pipe or conduit, or the bed and banks of a stream.

The force of liquid friction is found to be proportional to the heaviness of the liquid (i.e., to the weight of a cubic unit, such as a cubic foot), to the area of wetted surface over which the liquid flows, and nearly to the square of the velocity with which the liquid moves. Hence if _l■_ is the length of channel, _p_ the wetted portion of the perimeter of the cross-section, _w_ the weight of a cubic unit of the liquid, and _v_ the velocity, the total force of liquid friction for the length _l′_ of channel will be _F = ζwpl′v²_, ζ being the coefficient of liquid friction. The path of the force _F_ for a unit of time is _v_, and the work _W_ which it performs in that unit of time is equal to the weight _wal′_ falling through the height _h′_, _a_ being the area of the cross-section of the stream.

[Illustration: FIG. 2.]

Hence _W_ = ζ_wpl■v².v_ = _wal′h′._ (7)

_a_ _____ ____ ζ_v²v_ = ---- _h■_, _v_ = √(1/ζ) (_a/p_) (_h′/v_) = _c_√_rs_. (8) _p_

In this equation

_____ _a_ _c_ = √(1/ζ); _r_ = ---- = hydraulic mean radius; _p_ _h■_ _s_ = ----- = sine of inclination of stream’s bed. _v_

As the motion of the water is assumed to be uniform, the head lost by friction for the total length of channel _l_ is the total fall _h_, and by equation (8), since

_h′ h_ --- = _s_ = ---, _v l_

_v² l_ _h_ = ---- ---------. (9) _c²_ (_a/p_)

If, as in the case of the ordinary cast-iron water-pipes of a public supply system, the cross-section _a_ is circular,

_a_ (π_d²_/4) _d_ --- = --------- = ---, _p_ π_d_ 4

and

4.2_g l v² l v²_ _h_ = ----- --- ------ = _f_ --- -----, (10) _c² d_ 2_g d_ 2_g_

in which _f_ = 8_g_ ÷ _c²_.

The quantity _f_ is sometimes called the “friction factor.” For smooth, new pipes from 4 feet down to 3 inches in diameter its value may be taken from .015 to .03. An approximate mean value may be taken at .02.

The last member of equation (8) is Chezy’s formula, and it is one of the most used expressions in hydraulic engineering. Some values for the coefficient _c_ will presently be given. The quantity _r_ found by dividing the area of the cross-section of the stream by the wetted portion of its perimeter is called the “hydraulic mean radius,” or simply the “mean radius.” The other quantity, _s_,

appearing in the formula is, as shown by the figure, the sine of the inclination of the bed of the stream.

In order to determine the discharge of any pipe, conduit, or open channel carrying a known depth of water, it is only necessary to compute _r_ and _s_ from known data and select such a value of the coefficient _c_ as may best fit the circumstances of the particular case in question. The substitution of those quantities in Chezy's formula, i.e., equation (8), will give the mean velocity _v_ of the water which, when multiplied by the area of cross-section of the stream, will give the discharge of the latter per second of time. It is customary to compute _r_ in feet. The coefficient _c_ is always determined so as to give velocity in feet per second of time. Hence if the area of the cross-section of the stream, _a_, is taken in square feet, as is ordinarily the case, the discharge _av_ will be in cubic feet per second.

[Illustration: Progress View of Construction of New Croton Dam.]

=187. Kutter's Formula.=—The coefficient _c_ in Chezy's formula is not a constant quantity, but it varies with the mean radius _r_, with the sine of inclination _s_, and with the character of the bottom and sides of the open channel, i.e., with the roughness of the interior surface of the closed pipe. Many efforts have been made and much labor expended in order to find an expression for this coefficient which may accurately fit various streams and pipes. These efforts have met with only a moderate degree of success. The form of expression for _c_ which is used most among engineers is that known as Kutter's formula, as it was established by the Swiss engineer W. R. Kutter. This formula is as follows:

$$c = \frac{(1.811 + \frac{.00281}{n} + \frac{41.65}{s})\sqrt{r}}{1 + (\frac{n}{\sqrt{r}})(.00281 + \frac{41.65}{s})}$$

The quantity _n_ in this formula is called the "coefficient of roughness," since its value depends upon the character of the surface over which the water flows. It has the following set of values for the surfaces indicated:

_n_ = 0.009 for well-planed timber; _n_ = 0.010 for neat cement; _n_ = 0.011 for cement with one third sand; _n_ = 0.012 for unplaned timber; _n_ = 0.013 for ashlar and brickwork; _n_ = 0.015 for unclean surfaces in sewers and conduits; _n_ = 0.017 for rubble masonry; _n_ = 0.020 for canals in very firm gravel; _n_ = 0.025 for canals and rivers free from stones and weeds; _n_ = 0.030 for canals and rivers with some stones and weeds; _n_ = 0.035 for canals and rivers in bad order.

=188. Hydraulic Gradient.=—Before illustrating the use of Chezy's formula in connection with masonry and metal conduits, of which mention has already been made, it is best to define another quantity constantly used in connection with closed iron or steel pipes. This quantity is called the "hydraulic gradient." If a closed iron or steel pipe is running full of water and under pressure and if small vertical tubes be inserted in the top of the pipe with their lower ends bent so as to be at right angles to its axis, the water will rise to heights in the tubes depending upon the pressures of water in the pipe or conduit at the points of insertion. Such tubes with the water columns in them are called piezometers. They are constantly used in connection with water-pipes in order to show the pressures at the points where they are inserted. A number of such pipes being inserted along an iron pipe or conduit, a line may be imagined to be drawn through the upper surfaces of the columns of water, and that line is called the "hydraulic gradient." It represents the upper surface of water in an open channel discharging with the same velocity existing in the closed pipe.

In case Chezy's formula is used to determine the velocity of discharge in a closed pipe running under pressure, the sine of inclination _s_ must be that of the hydraulic gradient and not the sine of inclination of the axis of the closed pipe. In the determination of this quantity _s_ by the use of piezometer tubes, if a straight pipe remains of constant section between any two points, it is only necessary to insert the tubes at those points and observe the difference in levels of the water columns in them. That difference of levels or elevations will represent the height which is to be divided by the length of pipe or conduit between the same two points in order to determine the sine _s_.

[Illustration: Progress View of Construction of New Croton Dam.]

The hydraulic gradient plays a very important part in the construction of a long pipe-line or conduit. If any part of the pipe should rise above the hydraulic gradient, the discharge would no longer be full below that point. It is necessary, therefore, always to lay the pipe or the closed conduit so that all parts of it shall be below the hydraulic gradient. Caution is obviously necessary to lay a pipe carrying water deep enough below the surface of the ground in cold climates to protect the water against freezing. At the same time if the pipe-line is a long one it must follow the surface of the ground approximately in order to save expensive cutting. There will, therefore, generally be summits in pipe-lines, and inasmuch as all potable water carries some air dissolved in it, that air is liable to accumulate at the high points or summits. If that accumulation goes on long enough, it will seriously trench upon the carrying

capacity of the pipe and decrease its flow. It is therefore necessary to provide at summits what are called blow-off cocks to let the air escape. At the low points of the pipe-line, on the contrary, the solid matter, such as sand and dirt, carried by the water is liable to accumulate, and it is customary to arrange blow-offs also at such points, so as to enable some of the water to escape and carry with it the sand and dirt.

=189. Flow of Water in Large Masonry Conduits.=—In order to apply Chezy's formula first to the flow of the masonry aqueducts of the New York and Boston water-supplies, it is necessary to have the outlines of those conduits so that the wetted perimeter and hence the mean radius may be determined for any depth of water in them.

[Illustration: OUTLINES OF AQUADUCTS.

FIG. 3.]

The figure shows the desired cross-sections drawn carefully to scale. Table XIV has been computed and arranged from data taken from various official sources so as to show the depth, mean velocity, discharge per second and per twenty-four hours, and the coefficient used in Chezy's formula, together with the coefficient of roughness _n_ in Kutter's formula for the conduits shown in the figure.

This table exhibits in a concise and clear manner the use of Chezy's formula in this class of hydraulic work.

† From report by J. R. Freeman to B. S. Coler, 1899. ‡ From report of New York Aqueduct Commission.

=190. Flow of Water through Large Closed Pipes.=—The masonry conduits to which consideration has been given in the preceding paragraphs carry water precisely as in an open canal, but the closed conduits or pipes of steel plates and cast-iron, like the Hemlock Lake conduit at Rochester and the East Jersey conduit of the Newark Water-works, are of an entirely different type, as they carry water under pressure. Hence the slope or sine of inclination _s_ belongs to the hydraulic gradient rather than to the grade of the pipe itself. Where the pipe-line is a long one its average grade frequently does not differ much from the hydraulic gradient, but the latter quantity must always be used. As in the case of the masonry conduits, the coefficient _c_ in Chezy's formula

will vary considerably with the degree of roughness of the interior surface of the pipe, with the slope _s_, and with the mean radius _r_. An important distinction must be made between riveted steel pipes and those of cast-iron, for the reason that the rivet-heads on the inside of the former exert an appreciable influence upon the coefficient _c_. The rivet-heads add to the roughness or unevenness of the interior of the pipe. Table XV gives the elements of the flow or discharge in the two pipe-lines which have been taken as types, as determined by actual measurements; it also exhibits similar elements for timber-stave pipes, to which reference will be made later.

[Illustration: CROTON AQUEDUCT

IN EARTH.]

As would be expected, the velocity of flow in these pipes may be and generally is considerably higher than the velocity of movement in masonry channels. Both Tables XV and XVI give considerable range of coefficients computed and arranged from authoritative sources, and the coefficients _c_ for Chezy's formula represent the best hydraulic practice in connection with such works at the present time. In using the formula for any special case, great care must be taken to select a value for _c_ which has been established for conditions as closely as possible to those in question. This is essential in order that the results of estimated discharges may not be disappointing, as they sometimes have been where that condition so necessary to accuracy has not been fulfilled.

=191. Change of Hydraulic Gradient by Changing Diameter of Pipe.=—It has already been seen, in the case of closed pipes or conduits, that the hydraulic gradient with slope _s_ governs the velocity of flow, and also that all parts of the pipe-line must be kept below that gradient. It is sometimes desirable, in order to meet conditions either of topography or of flow, to raise or lower the hydraulic gradient over the whole or some portion of the pipe-line. This can easily be done to any needed extent by varying the diameter of the pipe. An increase in diameter will in general decrease the velocity of the water and increase its pressure, thus increasing correspondingly the height of the columns of water in the piezometer tubes. As the top surface of the latter determines the hydraulic gradient, it is seen that increasing the diameter of a portion of the pipe-line will correspondingly raise the gradient over the same portion. Thus by a proper relative variation of diameters the hydraulic gradient of a given pipe-line may readily be controlled within sufficient limits to meet any ordinary requirements of this character.

=192. Control of Flow by Gates at Upper End of Pipe-line.=—Obviously, if the pressure in the pipe-line is diminished, less thickness of metal will be required to resist it, and a corresponding degree of economy may be reached by a decrease in the quantity of metal. In the 21 miles of 48-inch steel-plate pipe of the East Jersey Water Company there is a fall of 340 feet; if, therefore, the flow through that pipe were regulated by a gate or gates at its lower end, the lower portion of the line would be subjected to great intensity of pressure. If, however, the flow through the pipe is controlled by a gate or gates at its upper end, enough water only may be admitted to enable it to flow full with the velocity due to the hydraulic gradient. By such a procedure the pressure upon the pipe over and above that which is necessary to produce the gradient is avoided. This condition is not only judicious in the reduction of the amount of metal required, but also in reducing both the leakage and the tendency to further leakage, which is largely increased by high pressures. This feature of control of pressure in a long pipe-line with considerable fall is always worthy of most careful consideration.

=193. Flow in Old and New Cast-iron Pipes—Tubercles.=—The velocity of flow through cast-iron mains or conduits or through the cast-iron pipes of a distribution system of public water-supply depends largely upon the condition of the interior surface of the pipes as affected by age. All cast-iron pipes before being shipped from the foundry where they are manufactured are immersed in a hot bath of suitable coal-tar pitch composition in order to protect them from corrosion. After having been in use a few years this coating on the interior of the pipes is worn off in spots and corrosion at once begins. The iron oxide produced under these circumstances forms projections, or tubercles as they are called, of greatly exaggerated volume and out of all proportion to the actual weight of oxide of iron. When the pipes are emptied these tubercles are readily removed by scraping, but before their removal they greatly obstruct the flow of water through the pipes. Indeed this obstruction is so great that the discharging capacity of cast-iron mains must be treated in view of its depreciation from this source.

Table XVII exhibits the value of the coefficient _c_ to be used in Chezy's formula for all cast-iron pipes having been in use for the periods shown.

TABLE XVII.

TABLE OF VALUES OF _f_ AND _c_. LEGEND: (A) = Diameter, Inches. (B) = Hydraulic Radius _r_, Inches. (C) = Velocity, Feet per Second. (D) = Coefficient _c_. (E) = Coefficient _f_. ---------+-------------------------+-----+----+-----+-----+------ | | | | | Authority.|

Pipe-line. | | | | | | | (A) |(B) | (C) | (D) | (E) | | | | | | --------+------------------------+-----+----+-----+-----+------ Darcy |New Pipe | 3.22| .8 | 0.29| 78.5| .0418 | | | |10.71|100.0| .0257 --------+------------------------+-----+----+-----+-----+------ Darcy |Old cast-iron pipe lined | 9.63|2.41| 1.00| 72.5| .0489 | with deposit | | |12.42| 74.0| .0468 --------+------------------------+-----+----+-----+-----+------ Darcy |Pipe above cleaned | 9.63|2.41| 0.91| 90.0| .0316 | | | |14.75| 98.0| .0269 --------+------------------------+-----+----+-----+-----+------ Brush |Cast-iron pipe tar-coated|20 |5 | 2.00|114.0| .0197 | and in service 5 years. | | | 3.00|110.0| .0214 --------+------------------------+-----+----+-----+-----+------ Darrach |Cast-iron pipe in service|20 |5 | 2.71| 67.5| .0568 | 11 years | | | 5.11| 83.0| .0376 --------+------------------------+-----+----+-----+-----+------ Darrach |Cast-iron pipe in service|36 |9 | 1.58| 60.0| .0716 | 7 years | | | 2.37| 66.0| .0586 --------+------------------------+-----+----+-----+-----+------

Obviously it is not possible to clean the smaller pipes of a distribution system, but large cast-iron conduits may be emptied at suitable periods and have their interior surfaces cleaned of tubercles or other accumulations. At the same time, if necessary, a new coal-tar coating can be applied.

Table XVIII exhibits the values of the coefficient _c_ to be used in Chezy's formula for new and clean coated cast-iron pipes. It represents the results of actual hydraulic experience and is taken from Hamilton Smith's "Hydraulics." A comparison between this table and that which precedes will show how serious the effect of tubercles may be on the discharging capacity of a cast-iron pipe.

____ In using Chezy's formula, _v_ = _c_√_rs_,

in connection with either Table XVII or XVIII, the slope or sine of inclination _s_ of the hydraulic gradient may be readily computed by equation (10), which gives the head lost by friction in a closed circular pipe as

_l v²_ _h_ = _f_ - --- ----. _d_ 2_g_

It is only necessary in a straight pipe or one nearly straight to compute the quantity

_h f v²_ _s_ = --- = --- ------. _l d_ 2_g_

TABLE XVIII.

=194. Timber-stave Pipes.=—In the western part of the country long conduits or pipe-lines are frequently constructed of timber called redwood. Staves of suitable thickness, sometimes 1¾ inches, are accurately shaped and finished with smooth surfaces so as to form large pipes of any desired diameter. These staves are held rigidly in place with steel bands drawn tight with nuts on screw ends, so as to close tightly the joints between them. Such wooden conduits are rapidly and cheaply built and are very durable. They have the further advantage of requiring no interior coating, as the timber surface remains indefinitely unaffected by the water flowing over it. The latter part of Table XV shows coefficients for Chezy's formula which may be used for such a class of timber conduits. As the interior surfaces of such closed conduits are always very smooth, the coefficients are seen to be relatively large, and such pipes are, therefore, well adapted to maintain unimpaired discharging capacity for great lengths of time.

CHAPTER XVIII.

=195. Pumping and Pumps.=—When it is impossible to secure water at sufficient elevation to be delivered to the points of consumption by gravity, it is necessary to resort to pumping in order to raise it to the desired level. Indeed it is sometimes necessary to resort to pumping in connection with a gravity supply in order to deliver water to the higher parts of the distribution system, the lower points being supplied by gravity. This combination of gravity supply with pumping is not unusual. That part of New York north of Thirty-fourth Street between Lexington and Fifth avenues, north of Thirty-fifth Street between Fifth and Sixth avenues, north of Fifty-first Street between Sixth and Ninth avenues, north of Fifty-fifth Street between Ninth and Tenth avenues, north of Fifty-eighth Street between Tenth and Eleventh avenues, and north of Seventy-second Street between Eleventh Avenue and the North River, with elevation of 60 feet or more above mean high tide-water, is supplied from the high-service reservoir near High Bridge, the water being elevated to it from the Croton supply by the pumping-station at the westerly end of the bridge. The elevation of the water surface in the High Bridge reservoir is 208 feet, and that of the large reservoir in Central Park 115 feet, above mean high tide-water. Some specially high points on the northern part of Manhattan Island are supplied from the High Bridge tower, whose water surface is 316 feet above mean high tide.

[Illustration]

[Illustration: Skeleton Pumps.]

The pumps employed for the purpose of elevating water to distributing-reservoirs are among the finest pieces of machinery built by engineers at the present time. They are usually actuated by steam as a motive power, the steam being supplied from suitable boilers or batteries of boilers in which coal is generally used as fuel. The modern pumping-engine is in reality a combination of three classes of machinery, the boilers, the steam-engines, and the pumps. There are various types of boilers as well as of engines and pumps, all, when judiciously designed and arranged, well adapted to the pumping-engine process. The pumps are generally what are called displacement pumps; that is, the water in the pump-cylinder is displaced by the reciprocating motion of a piston or plunger. These pumps may be either double-acting or single-acting; in the former case, as the piston or plunger moves in one direction it forces the water ahead of it into the main or pipe leading up to the reservoir into which the water is to be delivered, while the water rising from the pump-well follows back of the piston or plunger to the end of its stroke. When the motion is reversed the latter water is forced on its way upward through the main, while the water rises from the pump-well into the other end of the water-cylinder. In the case of single-acting pumps water is drawn up into the water-cylinder from the pump-well during one stroke and forced up through the main during the next stroke, one operation only being performed at one time. The pump-well is a well or tank, usually of masonry, into which the water runs by gravity and from which the pump raises it to the reservoir. For the purposes of accessibility and convenience in repairing, the pump is always placed at an elevation above the water in the pump-well, the pressure of the atmosphere on the water in the well forcing the latter up into the pump-cylinder as the piston recedes in its stroke. The height of a column of water 1 square inch in section representing the pressure of the atmosphere per square inch is about 34 feet, but a pump-cylinder should not be placed more than about 18 feet above the surface of the water in the pump-well in order that the water may rise readily as it follows the stroke of the plunger.

In the operation of the ordinary pump the direction of the water as it flows into and out of the pump-cylinder must necessarily be reversed, and this is true also with the type of pump called the differential plunger-pump, which is really a single-acting pump designed so as to act in driving the water into the main like a double-acting pump, i.e., both motions of the plunger force water through the main, but only one draws water from the pump-well into the pump-cylinder. Valves may be so arranged in the pump-piston as to make the progress of the water through the pump continuous in one direction and so avoid the irregularities and shocks which necessarily arise to some extent from a reversal of the motion of the water.

The steam is used in the steam-cylinders of a pumping-engine precisely as in every other type of steam-engine. At the present time compound or triple-expansion engines are generally used, among the well-known types being the Worthington duplex direct-acting pump without crank or fly-wheel, the Gaskill crank and fly-wheel pumping-engine, the Allis and the Leavitt pumping-engines, both of the latter employing the crank and fly-wheel and both may be used as single- or double-acting pumps, usually as the latter. The characteristic feature of the well-known Worthington pumping-engine is the movement of the valves of each of the two engines by the other for the purpose of securing a quiet seating of the valves and smooth working.

One of the most important details of the pumping-engine is the system of valves in the water-cylinder, and much ingenuity has been successfully expended in the design of proper valve systems. These pump-valves must, among other things, meet the following

requirements as efficiently as possible: they must close promptly and tightly, so that no water may pass through them to create slip or leakage; they should have a small lift, so as to allow prompt closing, and large waterways, to permit a free flow through them with little resistance; they must also be easily operated, so as to require little power, and, like all details of machinery, they should be simple and easily accessible for repairing when necessary.

As steam is always used expansively, its force impelling the plunger will have a constant value during the early portion of the stroke only, and a much less value, due to the expansion of the steam, at and near the end of the stroke, while the head of water against which the pump operates is practically constant. There is, therefore, an excess of effort during the first part of the stroke and a deficiency during the latter part. Unless there should be some means of taking up or cushioning this difference, the operation of the pump would be irregular during the stroke and productive of water-hammer or blows to the engine. Two means are employed to remove this undesirable effect, i.e., the fly-wheel and the air-chamber, or both. In the one case the excess of work performed by the steam in the early part of the stroke is stored up as energy in the accelerated motion of the fly-wheel and given out by the latter near the end of the stroke, thus producing the desired equalization. The air-chamber is a large reservoir containing air, attached to and freely communicating with the force-main or pipe near its connection with the pumps. In this case the excess of work performed at the beginning of the stroke is used in compressing the air in the air-chamber, sufficient water entering to accomplish that purpose. This compressed air acts as a cushion, expanding again at the end of the stroke and reinforcing the decreasing effort of the steam.

=196. Resistances of Pumps and Main—Dynamic Head.=—Obviously the water flowing through the pipes, pump-cylinders, and pump-valves will experience some resistance, and it is one purpose in good pumping-engine design to make the progress of the water through the pump so direct and free as to reduce these losses to a minimum. Similarly the large pipe or main, called the force-main, leading from the pump up to the reservoir into which the water is delivered, sometimes several thousand feet long, will afford a resistance of friction to the water flowing through it. The head which measures this frictional loss is given by equation (10) on page 239. All these resistances will increase rapidly with the velocity with which the water flows through the pipes and other passages, as do all hydraulic losses. It is obviously advisable, therefore, to make this velocity as low as practicable without unduly increasing the diameter of the force-main. This velocity seldom exceeds about 3 feet per second.

[Illustration: Allis Pump.]

[Illustration: Section of Allis Pumping-Engine.]

The static head against which the pumping-engine operates is the vertical height or elevation between the water surfaces in the pump-well and the reservoir. The head which represents the resistances of the passages through the pump and force-main, when added to the sum of the static head and the head due to the velocity in the force-main, gives what is called the dynamic head; it represents the total head against which the pump acts. If _h_ represents the static head, _h■_ the head due to all the resistances, and _h″_ the head due to the velocity in the force-main, then the dynamic head will be

$$H = h + h_{\blacksquare} + h'' = h + f \frac{l}{d} \frac{v^2}{2g} + n \frac{v^2}{2g} + \frac{v^2}{2g},$$

in which _f_ has a value of about .015 and _n_ is a coefficient which when multiplied by the velocity head will represent the loss of head incurred by the water in passing through the pump-cylinder and valves. The latter quantity is variable in value; but it is seldom more than a few feet.

=197. Duty of Pumping-engines.=—It is thus seen that the collective machines and force-main forming the pumping system afford opportunity for a number of serious losses of energy found chiefly in the boiler, the engine, and the pump. The excellence of a pumping-plant, including the boilers, may obviously be measured by the amount of useful work performed by a standard quantity, as 100 pounds of coal. Sixty or more years ago, in the days of the old Cornish pumping-engine, the standard of excellence or “duty” was the number of foot-pounds of work, i.e., the number of pounds lifted one foot high, performed by one bushel of coal. As early as 1843 the Cornish pumping-engine reached a duty, per bushel of coal, of 107,500,000 foot-pounds. These pumping-engines were single-acting, the steam raising a weight the descent of which forced the water up the delivery-pipe.

At a later date and until about ten years ago the usual standard or criterion applied to pumping-engines for city water-works was the amount of work performed in lifting water for each 100 pounds of coal consumed; this result was also called the “duty” of the engine. In order to determine the duty of a pumping-engine it was thus only necessary to observe carefully for a given period of time, i.e., twenty-four hours or some other arbitrary period, the amount of coal consumed, the condition of the furnace-fires at the

beginning and end of the test being as nearly the same as possible, and measure at the same time the total amount of water discharged into the reservoir. The total weight of water raised multiplied by the total number of feet of elevation from the water surface in the pump-well to that in the reservoir would give the total number of foot-pounds of useful work performed. This quantity divided by the number of hundred pounds of coal consumed would then give what is called the “duty” of the pumping-engine.

=198. Data to be Observed in Pumping-engine Tests.=—Obviously it is necessary to observe a considerable number of data with care. No pump works with absolute perfection. A little water will run back through the valves before they are seated, and there will be a little leakage either through the valves or through the packing around the piston or plunger, or both sources of leakage may exist. That leakage and back-flow represent the amount of slip or water which escapes to the back of the plunger after having been in front of it. In well-constructed machinery this slip or leakage is now very small and may be but a small fraction of one per cent. Inasmuch as the amount of work performed by the steam will be the same whether this slip or leakage exists or not, the latter is now frequently ignored in estimating the duty of pumping-engines, the displacement of the piston or plunger itself being taken as the volume of water pumped at each stroke.

Again, in discussing the efficiency of the steam portion of the machinery the amount of partial vacuum maintained in the vacuum-pump, which is used to move the water of the condensed steam, is affected by atmospheric pressure, as is the work which is performed. Hence in complete engine tests it is necessary to observe the height of the barometer during the test. It is also necessary to observe the temperature of feed-water supplied to the boiler, and to use accurate appliances for ascertaining with the greatest exactness practicable the weight of dry steam used in the steam-cylinders and the amount of water which it carries. It is not necessary for the present purpose to discuss with minuteness these details, but it is evident from the preceding observations that the complete test of a pumping-engine involves the accurate observation of many data and their careful use in computations. The determination of the duty alone is but a simple part of those computations, and the duty is all that is now in question.

=199. Basis of Computations for Duty.=—It was formerly necessary in giving the duty of a pumping-engine to state whether the 100 pounds of coal was actually coal as shovelled into the furnace, or whether it was that coal less the weight of ash remaining after combustion. It was also necessary to specify the quality of coal used, because the heating capacity of different coals may vary materially. For these different reasons the statement of the duty of a pumping-engine in terms of a given weight of coal consumed involved considerable uncertainty, hence in 1891 a committee of the American Society of Mechanical Engineers, appointed for the purpose, took into consideration the best method of determining and stating the duty of a pumping-engine. The report of that committee may be found in vol. XII of the Transactions of that Society. The committee recommended that in a duty test 1,000,000 heat-units (called British Thermal Units or, as abbreviated, frequently B.T.U.) should be substituted for 100 pounds of coal. In other words, that the following should be the expression for the duty:

foot-pounds of work done Duty = ---------- × 1,000,000. total number of heat-units consumed

For some grades of coal in which 1,000,000 heat-units would be available for every 100 pounds the numerical value of the duty expressed in the new terms would be unchanged, but for other grades of coal the new expression of the duty might be considerably different.

=200. Heat-units and Ash in 100 Pounds of Coal, and Amount of Work Equivalent to a Heat-unit.=—The following table exhibits results determined by Mr. George H. Barrus (Trans. A. S. M. E., vol. XIV. page 816), giving an approximate idea of the total number of heat-units which are made available by the combustion of 100 pounds of coal of the kinds indicated:

Semibitumintous: George’s Creek Cumberland, Percentage of Ash. 1,287,400 to 1,421,700 6.1 to 8.6 Pocahontas, 1,360,800 to 1,460,300 3.2 to 6.2 New River, 1,385,800 to 1,392,200 3.5 to 5.7

Bituminous: Youghiogheny, Pa., lump, 1,294,100 5.9 Youghiogheny, Pa., slack, 1,166,400 10.2 Frontenac, Kan., 1,050,600 17.7 Cape Breton Caledonia, 1,242,000 8.7

Anthracite: 1,152,100 to 1,318,900 9.1 to 10.5

[Illustration: Worthington Pump.]

Each unit or B.T.U. represents the amount of heat required to raise one pound of water at 32° Fahr. 1° Fahr., and it is equal to 778 foot-pounds of work. In other words, 778 foot-pounds of work is said to be the mechanical equivalent of one heat-unit. The amount of work, therefore, which one pound of dry steam is capable of performing at any given pressure and at the corresponding

temperature may readily be found by multiplying the number of available heat-units which it contains, and which may be readily computed if not already known, by 778, or as in a pumping-engine duty trial, knowing by observation the number of pounds of steam at a given pressure and temperature supplied through the steam-cylinders, the number of heat-units supplied in that steam is at once known or may easily be computed. Then observing or computing the total weight of water raised by the pumping-engine, as well as the total head (the dynamic head) against which the pumping-engine has worked, the total number of foot-pounds of work performed can be at once deduced. This latter quantity divided by the number of million heat-units will give the desired duty.

[Illustration: Section of Worthington Pump.]

=201. Three Methods of Estimating Duty.=—At the present time it is frequently, and perhaps usually, customary to give the duty in terms of 100 pounds of coal consumed, as well as in terms of 1,000,000 heat-units. Frequently, also, the duty is expressed in terms of 1000 pounds of dry steam containing about 1,000,000 heat-units. As has sometimes been written, the duty unit is 100 for coal, 1000 for steam, and 1,000,000 for heat-units.

=202. Trial Test and Duty of Allis Pumping-engine.=—The following data are taken from a duty test of an Allis pumping-engine at Hackensack, N. J., in 1899 by Prof. James E. Denton. This pumping-engine was built to give a duty not less than 145,000,000 foot-pounds for each “1000 pounds of dry steam consumed by the engine, assuming the weight of water delivered to be that of the number of cubic feet displaced by the plungers on their inward stroke, i.e., to be 145,000,000 foot-pounds at a steam pressure of 175 pounds gauge.” The capacity of the engine was to be 12,000,000 gallons per twenty-four hours at a piston speed not exceeding 217 feet per minute. The engine was of the vertical triple-expansion type with cylinders 25.5 inches, 47 inches, and 73 inches in diameter with a stroke of 42¹/■■ inches, the single-acting plunger being 25.524 inches in diameter. The following data and figures illustrate the manner of computing the duty:

DUTY PER 1000 POUNDS OF DRY STEAM BY PLUNGER DISPLACEMENT.

1. Circumference of plungers, _Cl_ 80.1875 ins. 2. Length of stroke, 7 42.0625 ins. 3. Number of plungers (single-acting) 3 4. Aggregate displacement of plunger per revolution =

$$3_C^2l_ \text{ ------ } = _d_ \text{ } 64,4557.1 \text{ cu. ins. } 4\pi$$

5. Revolutions during 24 hours, _N_ 43,337 6. Weight of one cubic foot of water, _w_ 62.42 lbs. 7. Total head pumped against, _H_ 266.61 ft. 8. Total feed-water per 24 hours, _W_ 160,354 lbs. 9. Duty per 1000 lbs. of feed-water =

$$_d \times w\ H \times N_ \times 1000 \text{ ------ } \times \text{ ---------- } 1728\ _W_$$

$$266.61 \times 43,337 \times 1000 = 2,331,976 \times \text{ ---------- } = 168,027,200 \text{ ft.-lbs. } 160,354$$

10. Percentage of moisture in steam at engine-throttle valve 0.3 per cent.

$$168,027,200 \text{ 11. Duty per 1000 lbs. of dry steam, ---------- } = 168,532,800 \text{ } 0.997 \text{ ft.-lbs.}$$

DUTY PER MILLION HEAT-UNITS.

12. Average steam pressure at throttle above atmosphere. 173 lbs. 13. Average feed-water temperature. 78°.5 Fahr. 14. Total heat in one pound of steam containing 0.3 per cent. of moisture above 32° Fahr. 1,194.2 B. T. U. 15. Heat per lb. of feed-water above 32° Fahr. 46.5 ” ------- 16. Heat supplied per lb. of feed-water above 32° Fahr. 1,147.7 ” 17. Duty per lb. of feed-water. 168,027.2 ft.-lbs. 18. Duty per million B. T. U. 146,403,614 ”

=203. Conditions Affecting Duty of Pumping-engines.=—Manifestly the duty of a pumping-engine by whatever standard it may be measured will vary with the conditions under which it is made. A new engine running under the favoring circumstances of a short-time test may be expected to give a higher duty than when running under the ordinary conditions of usage one month after another. Hence it can scarcely be expected that the monthly performance, and much less the yearly performance, of an engine will show as high results as when tested for a day or two or for less time.

=204. Speeds and Duties of Modern Pumping-engines.=—The following table gives the piston or plunger speeds of a number of the best modern pumping-engines, and the corresponding duties, with the standards by which those duties are measured.

LEGEND: (A) = Piston Speed in Feet per Minute. (B) = Duty in Foot-pounds. ----------+------+----------+---------- Engine. | (A) | (B) | Expressed in ----------+------+----------+---------- Ridgewood Station, Brooklyn, | | |

These results show that material advances have been made in pumping-engine designs within a comparatively few years.

CHAPTER XIX.

=205. Distributing-reservoirs and their Capacities.=—The water of a public supply seldom runs from the storage-reservoir directly into the distributing system or is pumped directly into it, although such practices may in some cases be permissible for small towns or cities. Generally distributing-reservoirs are provided either in or immediately adjacent to the distributing system of pipes, meaning the water-pipes large and small which are laid through the streets of a city or town, and the service-pipes leading from the latter directly to the consumers.

The capacity ordinarily given to these distributing-reservoirs is not controlled by any rigid rule, but depends upon the local circumstances of each case. If they are of masonry and covered with masonry arches, as required for the reception of some filtered waters, they are made as small as practicable on account of their costs. If, on the contrary, they are open and formed of suitably constructed embankments, like the distributing-reservoirs of New York City in Central Park and at High Bridge, they are and should be of much greater capacity. The storage volume of the High Bridge reservoir amounts to 11,000,000 gallons, while that of the Central Park reservoir is 1,000,000,000 gallons. Again, the capacity of the old receiving-basin in Central Park is 200,000,000 gallons. These reservoirs act also as equalizers against the varying draft on the system during the different portions of the day and furnish all desired storage for the demands of fire-streams, which, while it lasts, may be a demand at a high rate. It may be approximately stated under ordinary circumstances that the capacity of distributing-reservoirs for a given system should equal from two or three to eight or ten days supply. It is advantageous to approach the upper of those limits when practicable. The volume of water retained in these reservoirs acts in some cases as a needed storage, while repairs of pumping-machinery or other exigencies may temporarily stop the flow into them. The larger their capacity the more effectively will such exigencies be met.

=206. System of Distributing Mains and Pipes.=—Gate-houses must be placed at the distributing-reservoirs within which are found and operated the requisite gates controlling the supply into the reservoir and the outflow from it into the distributing system. The latter begins at the distributing-reservoir where there may be one or two or more large mains, usually of cast-iron. These mains conduct the water into the branching system of pipes which forms a network over the entire city or town. A few lines of large pipes are laid so as to divide the total area to be supplied into convenient portions served by pipes of smaller diameter leading from the larger, so that practically every street shall carry its line or lines of piping from which every resident or user may draw the desired supply. Obviously, as a rule, the further the beginning of the distributing system is departed from in following out the ramifications of the various lines the smaller will the diameter of pipe become. The smallest cast-iron pipe of a distributing system is seldom less than 3 inches, and sometimes not less than 4 or 6 inches. There should be no dead ends in any distributing system. By a dead end is meant the end of a line of pipes, which is closed so that no water circulates through it. Whenever a branch pipe ceases it should be extended so as to connect with some other pipe in the system in order to induce circulation. The entire distributing system should therefore, in its extreme as well as central portions, constitute an interlaced system and not a series of closed ends. This is essential for the purity and potability of the water-supply. A circulation in all parts of the entire system is essential and it should be everywhere secured.

The diagram shows a portion of the distributing system of the city of New York. It will be noticed that there is a complete connection of the outlying portions, so as to make the interlacing and corresponding circulation as complete and active as possible.

[Illustration: FIG. 4.—New York City Distributing System.]

=207. Diameters of and Velocities in Distributing Mains and Pipes.=—In laying out a distributing system it will not be possible to base the diameters at different points on close computations for velocity or discharges based upon considerations of friction or other resistances, as the conditions under which the pipes are found are too complicated to make such a method workable. Approximate estimates may be made as to the number of consumers to be supplied at a given section of a main pipe, and

consequently what the diameter should be to pass the required daily supply so that the velocity may not exceed certain maximum limits known to be advisable. Such estimates may be made at a considerable number of what may be termed critical points of the system, and the diameters may be ascertained in that manner with sufficient accuracy. In this field of hydraulics a sound engineering judgment, based upon experience, is a very important element, as it is in a great many other engineering operations.

It will follow from these considerations that as a rule the larger diameters of pipe in a given distributing system will belong to the greater lengths, and it will be found that the velocities of water in the various parts of a system will seldom exceed the following limits, which, although stated with some precision, are to be regarded only as approximate:

For 4-inch pipe 23 feet per second. ” 6 ” ” 23 ” ” ” ” 8 ” ” 17 ” ” ” ” 11 ” ” 12 ” ” ” ” 12 ” ” 12 ” ” ” ” 16 ” ” 9 ” ” ” ” 20 ” ” 8 ” ” ” ” 24 ” ” 7 ” ” ” ” 30 ” ” 7 ” ” ” ” 36 ” ” 7 ” ” ” ” 48 ” ” 7 ” ” ” ” 60 ” ” 7 ” ” ”

=208. Required Pressures in Mains and Pipes.=—In designing distributing systems it is very essential so to apportion the pipes as to secure the requisite pressure at the various street services. Like many other features of a water-supply system no exact rules can be given, but it may be stated that at the street-level a pressure of at least 20 to 30 pounds should be found in resident districts, and from 30 to 35 or 40 pounds in business districts. The character and height of buildings affect these pressures to a large extent. Old pipe systems usually have many weak points, and while pressures requisite to carry water to the top of three- or four-story buildings are needed, any great excess above that would be apt to cause breaks and result in serious leakages. If the distributing system is one in which the pressure for fire-streams is to be found at the hydrants, then greater pressures than those named must be provided. In such cases the pressures in pipes at the hydrants should range from 60 to 100 pounds.

=209. Fire-hydrants.=—Fire-hydrants must be placed usually at street corners, if the blocks are not too long, and so distributed as to control with facility the entire district in which they are found. Unless fire-engines are used to create their own pressure, the lower the pressure at the hydrant the nearer together the hydrants must be placed. It is obvious, however, that when the pressure of the system is depended upon for fire-streams it is desirable to have the pressure comparatively high, so far as the hydrants are concerned, as under those conditions they may be placed farther apart and a less number will be required.

=210. Elements of Distributing Systems.=—The following table gives a number of statistics, exhibiting the elements of the distributing system of a considerable number of cities, including some pumping and meter data pertinent to the costs of pumping on the one hand and the extension of the use of meters on the other.

It contains information of no little practical value in connection with the administration of the distributing systems and the consumption of water in it. This table has been compiled by Mr. Chas. W. Sherman of the New England Water-works Association, and was published in the proceedings of that association for September, 1901. The service-pipes, varying from ½ to 10 inches in diameter, are of cast-iron, wrought-iron, lead, galvanized iron, tin-lined, rubber-lined, cement-lined, enamelled and tarred, the practice varying widely not only from one city to another, but in the same city.

CHAPTER XX.

=211. Sanitary Improvement of Public Water-supplies.=—In the preceding consideration of a public water-supply it has been virtually assumed that the water will reach consumers in the proper sanitary condition; but this is not always the case. With great increase of population and corresponding increase of manufacturing and other industries there arise many sources of contamination, so that pure spring- or river-water for public supplies becomes less available and at the present time in this country it is rarely to be had.

The legal responsibility of parties who allow sewage, manufacturing wastes, or other contaminating matter to flow into streams is already clearly recognized, and many cities and towns are required to dispose of their sewage and other wastes in such manner as to avoid polluting streams of water flowing past sewer outfalls or manufacturing establishments; but even these restraints are not sufficient. If a stream has once been polluted it can scarcely be considered safe as a supply for potable water for public or private purposes. There are certain diseases whose bacilli are water-borne and which are conveyed by drinking-water containing them; prominent among such diseases are typhoid fever and cholera. Experience has many times shown that these bacilli or disease germs may find their way from isolated country houses as well as from the sewage of cities into water that would otherwise be potable. Besides such considerations as these it is equally well known from engineering experience that many waters of otherwise fair quality carry the remains of organic matter in one shape or another which operate prejudicially to the physical condition of those who drink such water. It is therefore becoming more and more the conviction of civil engineers and sanitarians that there are few sources of potable water so free from some degree of pollution that the supplies drawn from them do not require treatment in order to put them into good condition for drinking. It is not intended in this observation to state that there are no streams or springs from which natural waters may not be immediately used for domestic purposes without improving them by artificial means, but it may be stated even at the present time that no water of a public water-supply should be used without treatment, unless the most thorough bacteriological examinations show that its sanitary condition is eminently satisfactory.

It is the common experience of many public water-supplies in this country that during certain seasons of the year, extending through the summer and autumn months, certain low forms of vegetation flourish, causing sometimes discoloration and always offensive tastes and odors. While such waters are usually not dangerous, they certainly are not desirable and may cause the human system to become receptive in respect to pathogenic bacilli. The tendency at the present time, therefore, is to consider the improvement of any water-supply that may be contemplated for any city or town.

=212. Improvement by Sedimentation.=—The two broad methods of improving the water of a public supply at the present time are sedimentation and filtration, the latter generally through clean sand, although sometimes other fine granular material or porous mass is used. The operation of sedimentation is carried on when water is allowed to stand absolutely at rest or to move through a series of basins with such small velocity that the greater portion of the solid material held in suspension is given an opportunity to settle to the bottom. All water which is taken from natural sources, whether surface or underground, carries some solid matter. Some waters, like spring-water or from an underground supply, are so clear as to be very nearly free from solid matter in suspension, but, on the other hand, there are waters, like those from silt-bearing rivers, which carry large amounts. Observations upon the Mississippi River at St. Louis have shown that the suspended matter may reach as much as 1000 parts in one million, although the quantity held in suspension is usually much less than that. Similar observations have been made upon other silt-bearing streams. Such large proportions of suspended solid matter are not usually found in streams used for potable purposes, but there are few surface sources of water-supply the water from which will not be sensibly improved by sedimentation in settling-basins or reservoirs.

The process of sedimentation is usually preliminary to that of filtration. If raw water, i.e., as it comes from its natural source, is conducted directly to filtration-beds, the amount of solid matter is frequently so great that the surface of the filter would be too quickly clogged; hence it is advisable in almost every case to subject to sedimentation any water which is designed to be treated subsequently by filtration.

The degree of turbidity is usually measured by means similar to those employed in gauging discoloration from vegetable matter. One method devised by Mr. Allen Hazen, to which allusion will again be made, is that in which the depth in inches is observed at

which a platinum wire 1 mm. in diameter and 1 inch long can be seen. The degree of turbidity is then represented by the reciprocal of that distance. The permissible turbidity estimated in this manner is taken by different authorities at different values running from .025 to .2. Water of this degree of turbidity appears, when seen through a glass, to be practically clear.

The rapidity with which sedimentation can be performed depends greatly upon the character and degree of comminution of the solid material. If it is coarse, comparatively speaking, it will quickly fall to the bottom; if the solid matter is clay of fine texture, it is dissipated through the water in an excessively high degree of diffusion and will remain obstinately suspended. This has been found to be the case at some points with the Ohio River water. Ordinarily sufficient sedimentation can be accomplished where the water remains at rest from twenty-four to forty-eight hours; in general, observations as to this matter, however, must be applied very cautiously. Water of the Mississippi River at St. Louis has been found to deposit nearly all of its sediment within twenty-four hours. At Cincinnati, on the other hand, the Ohio River water carries so fine a sediment that on an average not more than 75 per cent of it will be deposited in three days by unaided subsidence. Again, at Omaha the water of the Missouri River has been found to be turbid at the end of seventy-two hours. In some cases, as with the waters of the Delaware and Schuylkill at Philadelphia, a greater amount of subsidence has been found to exist at times at the end of twenty-four hours than after forty-eight hours. It is obvious that some special conditions must have produced such results that would not ordinarily occur in connection with the operation of sedimentation.

=213. Sedimentation Aided by Chemicals.=—In cases where simple unaided subsidence proceeds too slowly it can be accelerated by the introduction of suitable chemicals. At Cincinnati, for instance, it was found advantageous to introduce into the water before flowing into the settling-basins a small amount of alum or sulphate of alumina, depending upon the degree of turbidity, the average being about 1.6 grains per gallon, rising to perhaps 4 grains in floods. By these means a few hours of aided sedimentation would produce more subsidence than could be obtained in several days without the chemicals. A similar recommendation has been made for the purpose of improving the water-supply for the city of Washington, D. C., from the Potomac River. In other cases between 5 and 6 grains of lime per gallon have produced effective results.

=214. Amount of Solid Matter Removed by Sedimentation.=—Under adverse conditions, or with sediment which remains obstinately suspended, not more than 25 to 50 per cent of the solid material will be removed by sedimentation, but when the process is working satisfactorily, sometimes by the aid of chemicals acting as coagulants, 90 to 99 per cent even of the solid material may be removed. The operation of sedimentation has another beneficial effect in that the solid matter when being deposited carries down with it large numbers of bacteria, which, in some cases, have been observed to be 80 or 90 per cent of the total contents of the water. In other words, the subsidence of the solid matter clears the water of a large portion of the bacteria.

=215. Two Methods of Operating Sedimentation-basins.=—Sedimentation is carried on in two ways, one being the “fill-and-draw” method and the other the “continuous” method. In the former method a basin or reservoir is first filled with water and then allowed to stand while the subsidence goes on for perhaps twenty-four hours. The clear water is then drawn off, after which the reservoir is again filled. In the continuous method, on the other hand, water is allowed to flow into a single reservoir or series of reservoirs through which it passes at an extremely low velocity, so that its contents will not entirely change within perhaps twenty-four hours or more. In this method the clear water is continuously discharging at a comparatively low rate, the velocity in the reservoir being so small that the solid matter may be deposited as in the fill-and-draw method. Both of these methods are used, and both are effective. The choice will be dependent upon local conditions. In the continuous method the solid matter is largely deposited nearer the point of entrance into the reservoir, but more generally over the bottom in the fill-and-draw method. The velocity of flow in the reservoirs of the continuous method generally ranges between 0.5 inch and 2.5 inches per minute. Occasionally the velocity may be slightly less than the least of these values, and sometimes one or two inches more than the maximum value.

=216. Sizes and Construction of Settling-basins.=—The sizes of the settling-basins will obviously depend to a considerable extent upon the daily consumption of water. There is no general rule to be followed, but the capacity of storage volume of those actually in use run from less than 1 to possibly 14 or 15 days’ supply. Under ordinary circumstances their volumes may usually be taken from 5 to 6 or 8 days’ supply. Their shape should be such as to allow the greatest economy in the construction of embankments and bottoms. They may generally be made rectangular. Their depths is also a matter, to some extent, of constructive economy. The depth of water will usually be found between about 10 and 16 feet, it being supposed that possibly 2 or 3 feet of depth will be required for the collection of sediment. These basins must be water-tight. The bottom surfaces may be covered with concrete 6 to 9 inches thick, with water-tight firm puddle 12 to 18 inches thick underneath, resting on firm compacted earth. The inner embankment surfaces or slopes may be paved with 10- or 12-inch riprap resting on about 18 inches of broken stone over a layer of puddle of equal thickness with the bottom and continuous with it. Occasionally the bottom and sides may be simply puddled with clay and

lined with brick or riprap pavement, laid on gravel, or broken stone. It is only necessary that the sides and bottoms shall be tight and of such degree of hardness and continuity as to admit of thorough cleaning.

The bottoms of sedimentation-basins may advantageously not be made level. In order to facilitate cleaning away the solid matter settling on them, a valley or depression may be formed along the centre line to which the two portions of the bottom slope. A grade in this channel or central valley of 1 in 500 with slopes on either side of 1 in 200 or 1 in 300 will be effective in the disposition of the solid matter. At the lowest end of the central valley there should be suitable gates through which the accumulated sediment can be moved out of the basin. This sedimentary matter will in many cases be soft mud, but its movement will always be facilitated by the use of suitable streams of water. The frequency of cleaning will depend upon the amount of sediment carried by the water and upon its accumulation in the basin. Whenever its depth ranges from 1 to 2 or 3 feet it is removed.

Complete control of the entrance of the water to and its exit from the basin must evidently be secured by suitable gates or valves and other appliances required for the satisfactory operation of the basin. In some cases the cost of sedimentation-reservoirs with concrete bottoms and sides has risen as high as $9000 per million gallons of capacity; but where the cheaper lining has been used, as in the case of reservoirs at Philadelphia, the range has been from about $3300 to about $4300.

=217. Two Methods of Filtration.=—After the process of sedimentation is completed there will necessarily always be found the remains of organic matter and certain other polluting material which should be removed before the water is allowed to enter the distributing system. This removal is accomplished usually by filtration through clean sand, but occasionally through porous material, such as concrete slabs, porcelain, or other similar material. The latter processes are not much used at the present time, and they will not be further considered.

The filtration of water through sand is carried on by two distinct methods, one called slow sand filtration and the other rapid sand filtration. In the first method the water is simply allowed to filter slowly through beds of sand from 2 to 3 or 5 feet thick and suitably arranged for the purpose. In the second method special appliances and conditions are employed in such manner as to cause the water to flow through the sand at a much more rapid rate. The method of slow sand filtration will first receive attention.

=218. Conditions Necessary for Reduction of Organic Matter.=—The most objectionable class of polluting materials includes organic matter which from one source or another finds its way into natural waters. Such material has originally constituted or formed a part of living organisms and chemically consists of varying proportions of carbon, oxygen, hydrogen, and nitrogen. As found in public water-supplies it is usually in some stage of decomposition. The chemical operations taking place in these decompositions are more or less complicated, but in a general way it may be said that the first step is the oxidizing of the carbon which may produce either carbon monoxide or carbon dioxide and a combination of nitrogen with hydrogen as ammonia. When the conditions are favorable, i.e., when free oxygen is present, the ammonia may be oxidized by it, thus producing nitric acid and water. If, as is generally the case, suitable other substances, as alkalis, are present, the nitric acid combines with them, forming nitrates more or less soluble and essentially innocuous. It is therefore seen that the complete result is a chemical change from the original organic matter, offensive and possibly dangerously polluting, to gaseous and solid matter, the former escaping from the water and the latter either passing off unobjectionably in a soluble state or precipitating to the bottom as inert mineral matter. In order that these processes may be completely effective, two or three conditions are necessary, i.e., sunlight, free oxygen, and certain species of that minute and low class of organisms known as bacteria, the nature and conditions of existence of which have been scientifically known and studied within a period extending scarcely farther back than ten or fifteen years. The precise nature of their operations and their relations to the presence of the necessary oxygen, or just the parts which they play in the process of decomposition, are not completely known, although much progress has been made in their determination. It is positively known that their presence and that of uncombined oxygen are essential. Certain species of these bacteria will live and work only in the presence of sunlight and oxygen; these are known as aerobic bacteria. Other species, forming a class known as anaerobic bacteria, live and effect their operations in the absence of sunlight and oxygen in that offensive mode of decomposition which takes place in cesspools and other closed receptacles for sewage and waste matter. They play an essential part in what promises to be one of the most valuable methods of sewage-disposal in which the septic tank is a main feature.

=219. Slow Filtration through Sand—Intermittent Filtration.=—In the slow sand filtration method of purifying the water of a water-supply the aerobic bacteria only act. In order that their operations may be completed, free oxygen and sunlight are essential requisites, and the first of these is found in every natural water which can be considered potable. Any water which does not contain sufficient free oxygen for this purpose is to be regarded with suspicion, and generally cannot be considered suitable for domestic purposes. The amount of uncombined oxygen contained in any potable natural water is greatly variable and changes much with the

period of exposure in a quiet state, as well as with pressure and temperature. In the river Seine it has averaged nearly 11 parts in a million throughout the year, being lowest in July and August and highest in December and January. It has been found in the experimental work of the Massachusetts State Board of Health that free or dissolved oxygen in potable water may vary from 8.1 parts at 80° Fahr. to 14.7 parts by weight at 32° Fahr. in 1,000,000 at atmospheric pressure.

TYPICAL SECTIONS OF UNIT BEDS IN LAWRENCE CITY FILTER.

APRIL, 1901.

COPIED FROM PLAN FURNISHED BY A.D. MARBLE, CITY ENGINEER.]

In some cases where liability to dangerous contamination exists it may be advisable to increase the available supply of oxygen in the water by using a slow sand filter intermittently, as has been done at Lawrence, Mass. Instead of permitting a continuous flow of water through the sand, that flow is allowed for a period of 6 to 12 hours only, after which the filter rests and is drained for perhaps an equal period. During this intermission another filter-bed is brought into use in the same manner. Alternating thus between two or more filters, the flow in any one is intermittent. In this manner the oxygen of the air finds its way into the sand voids of each drained filter in turn and thus becomes available in the presence of suitable species of bacteria for reducing the organic matter in the water next passing through the filter. Intermittent filters operated in this manner are not much used, but the most prominent instance is that at Lawrence, Mass. At that place the water after being filtered is pumped to a higher elevation for use in the distribution system. The pumps have been run nineteen hours out of the twenty-four, and the water is shut off from the filters five hours before the pumps stop. The gate admitting water to the filter is open one hour before they start. Nine hours of each day the filter does not receive water, and rests absolutely about four hours.

=220. Removal of Bacteria in the Filter.=—The grains of the sand at and near the surface of a slow sand filter, within a short time after its operation is begun, acquire a gelatinous coating, densest at the surface and decreasing rapidly as the mass of sand is entered. This gelatinous coating of the grains is organic in character and probably largely made up of numerous colonies of bacteria whose presence is necessary for the reduction of the organic matter. It is necessary to distinguish between these species of bacteria and those which are pathogenic and characteristic of such diseases as typhoid fever, cholera, and others that are water-borne. Every potable surface-water and possibly all rain-water carry bacteria which are not pathogenic and which apparently accumulate in dense masses at and near the surface of the slow sand filter. As the water finds its way through the sand it loses its organic matter and its bacteria, both those of a pathogenic and non-pathogenic character. Potable water, therefore, is purified and rendered innocuous by the removal in the filter of all its bacteria, including both the harmless and dangerous.

=221. Preliminary Treatment—Sizes of Sand Grains.=—In designing filtration-works consideration must be given to the character of water involved. There are waters which when standing in open reservoirs exposed to the sunlight will develop disagreeable tastes and odors, and it may be necessary to give them preliminary treatment especially for the removal of such objectionable constituents.

The character and coarseness of the sand employed are both elements affecting its efficiency as a filtering material. It should not be calcareous, for then masses of it may be cemented together and injure or partially destroy the working capacity. Again, if it is too coarse and approaches the size of gravel, water may run freely through it without experiencing any purification. Much labor has been expended, especially by the State Board of Health of Massachusetts, in investigating the characteristics of sand and the sizes of grains best adapted to filter purposes. In that work it has become necessary to classify sands according to degrees of fineness or coarseness. The diameter of a grain of sand in the system of classification employed means the cube root of the product of the greatest and least diameters of a grain multiplied by a third diameter at right angles to the greatest and least. The “effective” size of

any given mass of sand means the greatest diameter of the finest 10 per cent of the total mass. There is also a term called the "uniformity coefficient." The uniformity coefficient is the quotient arising from dividing the greatest diameter of the finest 60 per cent of the mass by the greatest diameter of the finest 10 per cent of the same mass. These are arbitrary terms which have been reached by experience as convenient for use in classifying sands. Evidently absolute uniformity in size will be indicated by a uniformity coefficient of 1, and the greater the variety in size the greater will be the uniformity coefficient. Sands taken from different vicinities and sometimes even from the same bed will exhibit a great range in size of grain.

[Illustration: FIG. 5.—Sizes of Grain or Fineness of Sand.]

Fig. 5 represents the actual variety of size of grain as found in eight lots of sand among others examined in the laboratory of the Massachusetts State Board of Health. The vertical scale shows the per cent by weight of portions having the maximum grains less in diameter than shown on the horizontal line. The more slope, like No. 5 or 6, the greater is the variety in size of grain. Those lines more nearly vertical belong to sands more nearly uniform in size of grain.

=222. Most Effective Sizes of Sand Grains.=—Investigations by the Massachusetts State Board of Health indicate that a sand whose effective diameter of grain is .2 mm. (.008 inch) is perhaps the most efficient in removing organic matter and bacteria from natural potable waters. At the same time wide experience with the operation of actual filters seems to indicate that no particular advantage attaches to any special size of grain, so long as it is not too fine to permit the desired rate of filtration or so coarse as to allow the water to flow through it too freely. Experiments have shown that effective sizes of sand from .14 to .38 mm. in diameter possess practically the same efficiency in a slow sand filter. The action of the filter is apparently a partial straining out of both organic material and bacteria, but chiefly the reduction of organic matter in the manner already described and probably the destruction to a large extent of the bacteria, especially those of a pathogenic nature, although at the present time it is impossible to state the precise extent of either mode of action.

=223. Air and Water Capacities.=—Another important physical feature of filter-sands, especially in connection with intermittent filtration, is the amount of voids between the grains. When the intermittent filter is allowed to drain, so that the only water remaining in it is that held between the grains by capillary attraction, generally at the bottom of the filter unless the sand is very fine, the volume of the water which remains in the voids is called the water capacity of the sand. The remaining volume between the grains is called the air capacity of the same sand. It is evident that the air capacity added to the water capacity will make the total voids between the sand grains.

[Illustration: FIG. 6.]

Fig. 6 shows the amount of air and water capacities of the same sands whose sizes of grains are exhibited in Fig. 5. The depth of the sand is supposed to be 60 inches, as shown on the vertical line at the left of the diagram, while the percentages of the total volume representing the amounts of voids is shown on the horizontal line at the bottom of the diagram. Both air and water capacities for each sand are shown by the various numbered lines partially vertical and partially inclined. It will be observed that the fine sands No. 2 and No. 4 have large water capacities, the water capacity being shown by that part of the diagram lying below and to the left of each line. It will be noticed that No. 5 sand is made up of approximately equal portions of fine and coarse grains, the former largely filling the voids between the latter. This mixture, as shown by the No. 5 line, gives a very high water capacity and a correspondingly low air capacity. Obviously a sand with a high water capacity has a correspondingly low air capacity, and in general would not be a very good sand for an intermittent filter, since it is the purpose of the latter to secure in the voids between the sand grains as much oxygen as practicable whenever the filter may be at rest.

=224. Bacterial Efficiency and Purification—Hygienic Efficiency.=—As the function of a filter is to remove as far as possible the organic matter and bacteria of the applied water, there must be some criterion by which its efficiency in the performance of those functions can be expressed. The bacterial efficiency is represented by the ratio found by dividing the number of bacteria after filtration in a prescribed cubic unit, as a cubic centimeter, by the number which the same volume of raw water held before being applied to the filter. This is a rather misleading ratio, for the reason that the effluent water may contain bacteria of certain species which grow in the lower portions of a filter or in the drains which conduct the effluent from it. It is possible, therefore, that bacteria may be found in a filter effluent when all of the bacteria originally held in the water have been removed. Hence the ratio expressing what is called the bacterial purification arises from dividing the number of bacteria actually removed from a cubic centimeter of water by the filter by the number originally held by a cubic centimeter of raw water. The smaller the first of these ratios the higher the degree of efficiency. Extended experience, both in the filters of such laboratories as that of the Massachusetts State Board of

Health and with actual filters of public water-supplies, show that under attainable conditions of operation 98 to 100 per cent of all the bacteria originally found in the water may be removed.

There is also used the term hygienic efficiency which is used in connection with slow sand filters. This means simply the per cent of pathogenic bacteria removed by the filter, and there is good reason to believe that it is at least as high as the bacterial purification.

=225. Bacterial Activity near Top of Filter.=—The work of removal of bacteria and organic matter has been found by extended investigations to be performed almost entirely within 6 or 8 inches of the top surface of the sand; indeed the most active part of that operation is probably concentrated within less than 3 inches of the surface. At any rate the retained bacteria and nitrogenous matter are found to decrease very rapidly within a foot from the upper surface, below which stratum the quantity is relatively very small and its rate of decrease necessarily slow. A little of this nitrogenous or gelatinous matter is found to surround to a slight extent the sand grains found at the bottom of the filter. Some authorities have considered that the more steady uniform efficiency of the deeper filters is due to this effect.

=226. Rate of Filtration.=—The rate at which water can be made to flow through a slow sand filter is of economical importance, for the reason that the higher the rate the less will be the area required to purify a given quantity per day. Foreign engineers and other sanitary authorities advocate generally slower rates of filtration than American engineers are inclined to favor. The usual rate in Europe is not far from 1.6 to 2.5 million gallons per acre per day. There is also considerable range in this country, and the rate may reach 3 million gallons per acre per day. Indeed a considerable number of tests have shown that for short periods of time, at least, some waters may be efficiently filtered at rates as high as 7 to 8 million gallons per acre per day, but probably no American engineer is ready to introduce such high rates as yet. As a matter of fact the rate will depend considerably upon the character of water used. Clear water from mountain lakes and streams uncontaminated and carrying little solid material may be filtered safely and properly at much higher rates of filtration than river or other waters carrying more sediment and more organic matter. This principle is recognized both in Europe and in this country. It would appear from experience that slow sand filters at the present time with rates of 2.5 to 3 million gallons per acre per day may be employed for practically any water that may be considered suitable for a public supply, and that with these rates high degrees of both bacterial purification and hygienic efficiency may be reached.

=227. Effective Head on Filter.=—Inasmuch as the depth of sand ranges from perhaps 3 to 5 feet the water will experience considerable resistance in flowing through it. The distance in elevation between the water surface over the filter and that of the water as it leaves the filter measures the loss of head experienced in passing through the sand and the drainage-passages under it. It has been maintained by some foreign authorities that this loss of head should be not more than 24 to 30 inches; that a greater head would force the water through the sand at such a rate as to render desired purification impossible. Experience both in the laboratory and with public filters in this country does not appear to sustain that view of the matter; considerably greater heads than 30 inches have been used with entirely satisfactory results both as to the removal of organic matter and bacteria. It appears to be best so to arrange the flow of water through the sand and the underdrains as to avoid in either a pressure below the atmosphere, as in that case some of the dissolved air in the water escapes and produces undesirable disturbances in the sand, resulting in reduced efficiency. No precise rule can be given in respect to this feature of filtration, but it seems probable that satisfactory results may be obtained under proper working of filters with a loss of head not greater than the depth of water on the filter added to the depth of sand in it, although that maximum limit would ordinarily not be reached. The depth of water on the filter may be taken from 3 to 5 feet. In this country it is seldom less than the least of these limits, and perhaps not often equal to the greater limit.

=228. Constant Rate of Filtration Necessary.=—Care should be taken in the operation of filters to avoid any sudden change in the texture or degree of compactness of the sand. At the times when workmen must necessarily walk over the surface they should be provided with special broad-based footwear, so as to produce as little effect of this kind as possible where they step. Sudden changes in the degree of compactness cause correspondingly sudden changes in the rate of filtration, and such changes produce a deterioration of efficiency. This may be due to two or three reasons. Possibly such changes may open small channels through which water finds its way too freely; or the breaking of the gelatinous bond between the grains of sand may operate prejudicially. At any rate it is essential to avoid such sudden changes and maintain as nearly uniform a rate of filtration over the entire filter as possible. Again, the age of a filter affects to some extent its efficiency. A month or two of time is required, when a new filter is started, to attain what may be called its normal efficiency. Even after that length of time the filter gains in its power to retain and destroy bacteria. This action is particularly characteristic of filters formed of comparatively coarse sand.

=229. Scraping of Filters.=—More or less solid inert as well as organic matter accumulates on the surfaces of the slow sand filters, so that at the end of proper periods of time, depending upon the character of the water filtered, this surface accumulation must be

scraped off and removed together with the sand into which it has penetrated. In scraping the filter it is impossible to remove less than .25 or .5 inch of sand, and at least .5 to .75 inch is removed whenever a filter is scraped. Sometimes 1 or 2 inches may be removed. This sand may be washed and again placed upon the filter for use. The operation of scraping exhibits a fresh sand surface to the applied water. It has been held, particularly by foreign authorities, that this operation of scraping militates against the efficiency of the filter for the time being. The investigations of the Massachusetts State Board of Health and other experiences in this country do not confirm that view which is based on the assumption that the top nitrogenous film is essential to efficiency. These investigations have shown that this film is not necessary in intermittent filters; that in many instances no diminution of efficiency has resulted from a removal of the film to a depth of .3 inch; that even the presence of that film has not given efficiency to coarse sand when the coating was thick enough to completely clog the filter; and, further, that the material of this nitrogenous film is found at a depth of several inches below the surface. It is practically certain that the scraping to depths not exceeding 1 inch have no sensible effect upon the efficiency under proper management and operation of the filters. This is particularly true if the thickness of sand is from 3 to 5 feet. It is undoubtedly true that with very shallow sand filters from 1 to 2 feet in depth the scraping of the surface may have some effect upon bacterial efficiency.

It has been the custom in connection with some European filters to waste the water which first passes through after cleaning, but the usual practice in this country is to fill slowly the filter with filtered water from below and, after the sand is submerged, to permit it to stand a little while before use. Care taken in this manner will insure an efficiency to a freshly scraped filter sufficient to avoid any wastage.

=230. Introduction of Water to Intermittent Filters.=—Where intermittent filters are used it is of the greatest importance to conduct the water to them so as not to disturb the sand on their surfaces. This can readily be done in a number of ways. If the shape of the filter is not oblong, it will be advisable to form a number of main drains or passages in the sand from which smaller depressions or passages near together may lead the water to all parts of the surface. The flowing of the first water through these depressions will permit the entire surface to be covered so gradually as not to disturb the sand grains, and it is essential that such means or their equivalent be employed. If the filter is long and narrow in shape, the main ditch along one of the longer sides, with depressions at right angles to it or across the filter and near together, will be sufficient to accomplish the desired purpose. Obviously when filters are not intermittently used such precautions are not needed.

=231. Effect of Low Temperature.=—In the early days of the use of sand filters in this country it was frequently supposed that the low temperature of the winter caused decreased bacterial purification and a decrease in power to reduce organic material. It now appears that such is not the case. The effects of low temperature, such as is experienced in winters of this climate, may be overcome by temporarily covering the filters so that heavy ice cannot form and produce disturbances in one way or another prejudicial to efficiency of operation. The agencies which operate to reduce efficiency in cold weather are no longer believed to be those due to low temperature. They are rather indirect and mechanical, and may be readily overcome by the prevention of the formation of ice.

=232. Choice of Intermittent or Continuous Filtration.=—The process of slow sand filtration when continuous has been shown by experience to be entirely effective for ordinary potable waters, but in those cases where the amount of dissolved oxygen may be low and where the amount of organic matter is relatively high it may be advisable to resort to intermittent filtration. Neither method, however, can be depended upon to render potable a water which has been robbed of its free oxygen by an excessive amount of contaminated organic matter. Nor can these processes be expected to remove coloring matter produced by peaty soils or other conditions in which large amounts of vegetable matter have been absorbed by the water. The methods, therefore, have their limitations, although their field of application is sufficiently wide to cover nearly all classes of potable water.

=233. Size and Arrangement of Slow Sand Filters.=—Among the first questions to arise in the design of slow sand filters are their size and arrangement. The total area will be determined by the total daily draft and the rate of filtration. Rates of filtration running from 2.5 to 3 million gallons per acre per day, or even more, have been found satisfactory and are customary in this country. Having given, therefore, the total daily quantity required, it is only necessary to divide that by the rate of filtration per acre and the result will be the number of acres required for the total filter-bed surface. This net area, however, is not sufficient. Unless there is requisite storage of filtered water to meet the variation in the hourly draft for the day, the capacity of the filters must be sufficient to meet the greatest hourly rate, which must be taken at least 1½ times the average hourly demand during the day; indeed this is only prudent in any case.

Again, it is necessary to divide the total filter surface into small portions called beds, so that one or more of them may be withdrawn from use for cleaning or repairs, while a sufficient filter-area remains in operation to supply the greatest hourly draft. This surplus area will usually run from 5 to 20 per cent of the total area of the filter-beds, although for small towns and cities it may be much more. The sizes of the filter-beds will depend upon the local circumstances of each case. It is evident that as each single bed must have its individual set of appliances and its separating walls, the purpose of economy will be best served by making the beds as large as practicable. At the same time they must not be made too large, for in that case the portion out of use might form so large a percentage of the total area as to increase unduly the cost of the entire plant. A size of bed varying between .5 and 1.5 acres is frequently and perhaps generally found in foreign filtering-plants. If filter-beds range in area from .5 acre to 2 acres, the latter for large plants, the purposes of economy and convenience in administration will probably be well served. The grouping of the beds is an important consideration and will depend somewhat, at least, upon the shape of the plot of ground taken for the filters. It is advisable that the inlets to the different beds should, as far as possible, discharge from a single inlet-pipe or main. This will generally be most conveniently accomplished by making the beds rectangular in shape, grouped on each side of the supply-main, with their longest dimensions at right angles to it. This arrangement is illustrated by the grouping of the filter-beds in the Albany plant, shown in Fig. 7. In the case of a single oblong bed, like that at Lawrence, Mass., shown in Fig. 4, page 284, its relatively great length and small width makes it possible to run the main supply along one side, from which branch depressions with concrete bottoms enable the water to be distributed uniformly over its surface in the manner shown in the figure. It is further necessary to group the filter-beds, pumps, sand-cleaning appliances, and other portions of the plant, so that the ends of economy and efficient administration may be served in the highest degree. It is always necessary that these features of the whole filtration system should be carefully kept in view in laying out the entire plant.

=234. Design of Filter-beds.=—The preparation of the site for a group of filtration-beds also involves the consideration of a number of principal questions. In the first place, the depth required for the sand and underdrains will not be far from 5 feet, and there must be a suitable bottom prepared below the collecting-drains. Again, the depth of water above the sand may vary from 3 to 5 feet, making the total depth, including the bottom, of the filter proper about 10 or 11 feet, and this may represent the depth of excavation to be made. If the material on which the filter to be built is soft, it may be necessary to drive piles to support the superincumbent weight. The bottom must be made water-tight. This can be done either by the use of a layer of well rammed or packed clay, 1 to 2 feet in thickness, carrying 6 or 8 inches of concrete, or by a surface of paved brick or stone. If the sides of the filter-beds are of embankments with surface slopes, the latter may be protected in the same manner. If the sides are of walls of masonry, concrete is an excellent material to be used for the purpose.

[Illustration: FIG. 7.—Sedimentation-basin and Filter-beds at Albany, N. Y.]

[Illustration: Filtration-plant at Albany, N. Y.]

In designing the sides of filters or of the piers projecting up through the sand for the support of the roof, in case there is one, it is imperative that care be taken to prevent water from flowing down through the joints between the sand and the sides of piers or the masonry sides of the filter-beds. There should be no vertical joint of that character, but the faces of masonry in contact with the sand should both slope and be made in steps, so that any settlement of the sand will tend to close the joint, while the steps will prevent flow. Nor should there be angles in which sand is to be packed; filleted corners are far preferable and should be used.

=235. Covered Filters.=—It has become the custom where the best results are expected in cold climates, if not in all cases, to cover filters with masonry roofs of domes and cylindrical or groined arches supported on masonry columns. Such roofs are usually covered with earth to a depth of 1 to 2 or 3 feet. They prevent any injurious action on the sides of the filters produced by thick ice or the effects of such ice upon the upper portions of the sand. In summer they also protect against the baking and cracking of the upper surface of the sand when exposed to the sun and prevent, to a considerable extent, the growth of algæ in different portions of the beds. They are expensive, filters with masonry covers costing once and a half to twice as much as open filters, but they enhance the sanitary value of the water. The height of the masonry roof must be about 2 to 3 feet above the upper surface of the water and high enough to offer convenient access to the sand when it is to be cleaned and renewed. The length of span for the arches or domes is seldom more than 12 or 15 feet.

=236. Clear-water Drain-pipes of Filters.=—After the water has passed through the sand it must be withdrawn from the bottom of the filter with as little resistance as practicable. This necessitates, in the first place, the bottom of the filter to be so shaped as to induce the flow of the filtered water toward the lines of drain-pipes which are laid to receive it. These pipes consist of the main members and the branches, the main members being laid along the centres of the beds and the branches running from them. The

bottoms of the filters, therefore, should be formed with depressions in which the main pipes are laid, and with such grades as to expedite the movement of the water flowing through the branches. If the bottoms are of concrete, they can advantageously be made of inverted arches or domes, the drain-pipes being laid along the lines of greatest depression. In such cases the loads produced by the weight of the roof are more nearly uniformly distributed over the bottom. The sizes of the drains will be dependent upon the areas from which they withdraw water. It is advisable to make them rather large, in order that the water may flow through them more freely. They seldom need exceed 6 or 8 inches. They are preferably made of salt-glazed vitrified pipes laid with open joints, around and in the vicinity of which are placed gravel or broken stone, the largest pieces with a maximum diameter of 1 to 2 inches. The largest broken stone or coarsest gravel is near the pipe and should decrease in size as the drain-pipe is receded from, so that the final portions of the gravel farthest removed from the drains will not permit the filter-sand to pass into it. When properly designed and arranged, the loss of head in passing from the farthest points of a filter-bed to the point of exit from the filter will not exceed about .01 to .02 of a foot.

[Illustration: Interior of Covered Filter at Ashland, Wis.]

=237. Arrangement of the Sand at Lawrence and Albany.=—Above this gravel is placed the filtering-sand, about 4 feet thick in the Albany filter and 3 to 4 feet thick in the filter at Lawrence, Mass. The sand in the Albany filter was specified to have not “more than 10 per cent less than .27 mm.” in diameter and “at least 10 per cent by weight shall be less than .36 mm.” in diameter. Over the entire floor was spread not more than 12 inches of gravel or broken stone, the lower 7 inches consisting of broken stone or gravel with greatest diameter varying from 1 inch to 2 inches; the remaining 5 inches of the lower 1 foot was composed of broken stone or gravel decreasing from 1 inch in greatest diameter to a grain a little coarser than that of the sand above it. In all cases, sand for the filter-bed should be free from everything that can be classed as dirt, including clay, loam, and vegetable matter. Furthermore, it should be free from any mineral matter which might change the character of the water and render it less fit for use.

[Illustration: Partially Filled Covered Sand Filter showing Drain-pipe.]

This filtering-sand is usually placed in position with a horizontal surface. At Lawrence, however, it was placed with a wavy surface, the horizontal distance between the crests of two consecutive waves being 30 feet, the concrete gutter for admitting the water being half-way between, all as shown in the illustrations. The sand of this filter was of two grades, the coarser sand having an effective size of 0.3 mm. (.118 inch) and the finer an effective size of 0.25 mm. (.098 inch). The two different sizes of sand are seen not to be arranged in horizontal layers, but so that the finer is over the drains and the coarser between. The No. 70 sand is capable of passing 70 million gallons per acre per day with a head on it equal to the depth of sand, while the No. 50 sand can pass 50 million gallons per acre per day with a head on it equal to its depth. There appears to be no special advantage in placing the sand in filters other than in horizontal layers with an effective size practically uniform.

=238. Velocity of Flow through Sand.=—The velocity with which water will flow through a given depth of sand with a known depth or head above the surface of the latter has been carefully investigated by the Massachusetts State Board of Health with the following results:

_v_ = the velocity at which a solid column of water, whose section equals in area that of the bed of sand, moves downward through the sand in meters per day; this is practically the number of million gallons passing through the sand per acre per day. _c_ = a constant, having the value of 1000 for clean sand, and 800 for filter-sand after having been some time in use. _d_ = the effective size of the sand-grain in millimeters. _h_ = the head lost by the water in passing through the sand at the rate v; this is the effective head of water producing motion through the sand. _l_ = the thickness of the sand bed. _t_ = the temperature of the water in degrees Fahr.

The velocity _v_, as determined by experiment, takes the following form:

$$\frac{h}{l}(t + 10)\,v = cd^2 \quad \text{---} \quad (60)$$

This formula cannot be used for the flow of water through all sands of all thicknesses and under all circumstances. It is limited to effective diameters of sand between .1 and 3 mm., having a uniformity coefficient not greater than 5. _h_ and _l_ may be taken in any unit as long as both are expressed in the same unit, since the ratio of the two quantities will then not be affected. If the effective head of water on the filter or the head lost is equal to the thickness of the bed of sand, the ratio of _h_ divided by _l_ will be 1. In case the formula is used to express the quantity of water flowing through the sand per acre per day, it must be remembered that _v_ will be the number of million gallons and not the total number of gallons. The formula can only be used when the sand is well

compacted and where the voids of the sand are entirely filled with water.

=239. Frequency of Scraping and Amount Filtered between Scrapings.=—The frequency of the scraping of filters will depend upon the amount of organic matter in the water and upon the rate of filtration. Between the years 1893 and 1900 the periods between scrapings of the Lawrence filter ranged generally from 20 to 32 days, although periods as small as 13 or 19 are found in the records. The quantity of water passed between scrapings varies generally from 67 million to 90 million gallons, although it fell as low as 49 millions and rose as high as 109 millions. In the case of the Albany filter-plant, up to the end of the year 1900 the shortest period between scrapings was about 15 days and the longest about 42 days, the smallest quantity of water passing through any filter between scrapings being 26,735,000 gallons and the largest 76,982,000 gallons. The operation of the Albany filters for the year 1901 shows that the average run of a bed was 26 days between scrapings, with a total of 70,000,000 gallons per acre for that period. These figures represent about the usual workings of slow sand filters at the present time, the period between scrapings running usually between 15 and 30 days, and the quantity from 30 million gallons per acre to 100 million gallons per acre.

[Illustration]

[Illustration: Filters for City of Albany, N. Y.]

=240. Cleaning the Clogged Sand.=—The clogged sand scraped from the top of the filters at the periods of cleaning is removed to a convenient point where appliances and machinery are available for washing it. This is an item of some importance in the administration of filters, as the sand which is removed and washed is at a later period replaced upon the filter-bed. Various methods have been tried for the purpose of cleaning sand efficiently and economically. The continuous ejector sand-washer, one set of which is used at Albany, is probably as efficient as any machine yet devised. It is shown in Fig. 8. It will be observed that the dirty sand is fed to the machine at one end into a hopper-shaped receptacle. In the bottom of this hopper is a nozzle through which water is discharged from a pipe running along the entire bottom of the machine. This jet of water forces the sand upward through a suitable pipe into a reservoir which discharges the sand and water into another hopper, and so on through the series of five. Evidently there may be any number of hoppers in the series, a jet of water being provided at the bottom of each. In this manner the sand and water are thoroughly mixed together and compelled to flow upward from each hopper to the next, the dirty water overflowing also from each hopper into a tank underneath, whence it runs to waste. The clean sand and water flow out of the machine at the end opposite to that at which they entered. After the washed sand is dried it is ready to be replaced in the filter.

=241. Controlling or Regulating Apparatus.=—It is essential to the proper working of a slow sand filter that the amount of water admitted to and passing through it shall be as nearly uniform as practicable. This necessitates controlling or regulating apparatus, of which there are two general classes, the one automatic and the other worked by hand. There are a considerable number of appliances of both classes. The filtered water flows from the end of the drains to one or two small tanks formed by suitable masonry walls immediately outside of the filter-beds and rises to a level determined by the loss of head in passing through the filter. The difference in elevation between the water surface over the sand and that in the filtered water-tanks shows the effective head which causes the water to flow through the sand. The object of the controlling or regulating appliances is to keep that head as nearly constant as possible. Both the hand and automatic appliances preserve the value of that head by maintaining constant discharges through either vertical or horizontal orifices, the orifices themselves being movable. They may be rectangular or other orifices with horizontal lips or crests. If the control is automatic it is accomplished usually by a float which raises and lowers the orifice in such a way as to maintain a constant difference of level between the filtered and the unfiltered water. The figures illustrate both types of regulating appliances, the actions of which will be readily understood.

[Illustration: FIG. 8.—Ejector Sand-washer.]

[Illustration: FIG. 9.—Ball-float Regulator of Rate of Filtration.]

[Illustration: FIG. 10.—Regulator in Use in Zurich, Switzerland. M. Peter, Engineer.]

=242. Cost of Slow Sand Filters.=—The cost of both the open and covered slow sand filters will obviously vary according to the cost of labor and materials at their sites. The original cost of the Lawrence filter, about 2.44 acres in total area, was nearly $25,000 per acre. The cost of covered filters, so far as constructed in this country, varies from about $44,000 to nearly $51,000 per acre excluding the pipe, pumping plants, and sedimentation-basins. The Albany covered filters cost about $38,000 per acre including filtering materials, but excluding excavation, pumps, buildings, sedimentation-basins, piping, and sand-washing machinery, or nearly $46,000 per acre including those items except pumps and sedimentation-basins. The roof, included in the preceding

estimate, cost about $14,000 per acre. The smaller the filters the greater the cost per acre, as a rule, as would be expected. A single open filter at Poughkeepsie and three open filter-beds at Berwyn, Pa., cost respectively $42,000 and $36,000 per acre, the former being little less than .7 acre in area and the latter having an aggregate area of a little more than one half acre. A covered filter at Ashland, Wis., consisting of three beds of one sixth acre each, cost at the rate of about $70,000 per acre.

[Illustration: FIG. 11.—Regulating Apparatus Designed by Allen Hazen for the Albany Filters.]

[Illustration: FIG. 12.—Regulator of Rate of Filtration.]

=243. Cost of Operation of Albany Filter.=—The cost of operating the Albany filter, including only the costs of scraping, removing sand, refilling, incidentals, lost time, and washing the sand during seventeen months ending December 29, 1900, was $1.66 per million gallons filtered. The cost of removing the sand (excluding scraping), washing, and refilling was $1.21 per cubic yard. The total cost of operating the entire filter-plant, including all items, for the year 1900 was $4.52 per million gallons filtered. This covers all expenses, including pumping, superintendence, and laboratory, which can be charged to the operation of the filter-plant. The average removal of albuminoid ammonia at Albany for the year 1900 was 49 per cent and of the free ammonia 78 per cent of that in the raw water, while the average bacterial removal was over 99 per cent, running from 98.3 per cent to 99.6 per cent. The volume of water used in washing the sand was about twelve and a half times the volume of the sand. Each cubic yard of sand washed, therefore, required twelve and a half cubic yards of water.

[Illustration: FIG. 13.—Regulator Designed by W. H. Lindley for the Filters at Warsaw, Poland.]

=244. Operation and Cost of Operation of Lawrence Filter.=—It was originally intended that the Lawrence filter should be worked intermittently. The Merrimac River water, which is used by the city of Lawrence, was known to carry at certain periods of the year sufficient typhoid germs received from the city of Lowell to produce at least mild epidemics. The intermittent operation was considered necessary to furnish the filter with the requisite oxygen to destroy beyond a doubt all pathogenic bacteria. The increasing demands of water consumption during the years that have elapsed since filtration began in 1894 have seriously modified these conditions, so that the intermittent feature of operation of the filter is no longer very prominent. During 1898, for instance, the filter was drained only four to thirteen times per month, with an average of eight monthly drainings. In 1899 the drainings were more frequent, varying from five to fourteen per month and averaging eleven times. Finally, in 1900, the monthly drainings ranged from three to thirteen, with an average of eight. It may be considered, therefore, that the Lawrence filter occupies a kind of intermediate position between intermittent and continuous operation.

The total cost of operating the filter at Lawrence, including scraping and washing of sand, refilling, removal of snow and ice, and general items in the period from 1895 to 1900, both inclusive, varied from a minimum of $7.70 per million gallons to $9.00 per million gallons. If the removal of snow and ice be omitted, these amounts will be reduced to $5.10 and $6.90 respectively. The cost of washing the sand only in the Lawrence filter during the same period varied from 45 to 67 cents per cubic yard. The volume of water required for that washing varied from ten to fourteen times the volume of sand.

=245. Sanitary Results of Operation of Lawrence and Albany Filters.=—The average number of bacteria in the Merrimac River water applied to the filter during the period 1894 to 1899, both inclusive, varied from about 1900 per cubic centimeter to 34,900, and the percentage of reduction attained by passing the water through the filter varied in the same period generally from 97 to 99.8 per cent, with an average of about 99.1 per cent.

In the city of Lawrence the average number of cases of typhoid fever per 10,000 of population has been about one third, since the introduction of filtered water, of the number of cases which existed prior to the installation of the filters, and less than one fourth as many deaths. A large number of the cases of typhoid occurring after the installation of the filter have been traced to the use of unfiltered water, and it is probable that all or nearly all could be similarly accounted for.

In the city of Albany the experience had been quite similar. The average number of deaths per year from typhoid fever for ten years before the introduction of filtered water was 84, while in 1900, with the filter in operation, the total number of deaths was 39. These figures are sufficient to show the marked beneficial effect of filtered water on the public health.

[Illustration: Jewell Filter.]

=246. Rapid Filtration with Coagulants.=—It has been seen that the rate of filtration through open sand filters does not usually exceed 2 to 4 million gallons per acre per day under ordinary circumstances. Much greater rates would clog the sand and produce

less efficient results. Experience has also shown that such methods cannot be depended upon to remove from water coloring matter of a vegetable origin or very finely divided sediment. In order to accomplish these ends it is necessary to employ suitable chemicals which, acting as coagulants, may accomplish results impracticable in the open filter. Resort has therefore been made first to the adoption of suitable coagulants and then to such increased heads or pressures as to force the water through the sand at rates from 25 to 30 or even 50 times as great as practicable in slow sand filtration. These rapid sand filters are called mechanical filters. If the water is forced through them under pressure, they consist of closed tanks in which sand is placed so as to leave sufficient volume above it for the influent water and, supported upon a platform carrying perforated pipes, strainers, or equivalent details through which the filtered water may flow into a suitable system of effluent pipes in the lower part of the filter. If water is forced through the sand by the required head, the upper part of the filter may be open, but of sufficient height to accommodate it. The same filtering material, clean sand, is used as in the slow filters; the only differences, aside from the higher rate of filtration, are the greater head and the introduction of a coagulant to the water. The depth of sand used may vary from 2 to 4 feet. The thickness of a relatively fine sand may be less than that of a coarser sand.

=247. Operation of Coagulants.=—The coagulant which has been found to give the best results is ordinary alum or sulphate of aluminum. If sulphate of aluminum is dissolved in water containing a little lime or magnesia, aluminum hydrate and sulphuric acid are formed. The aluminum hydrate is a sticky gelatinous substance which gathers together in a flocculent mass the particles of suspended matter in the water, and it also adheres to the grains of sand when those masses have settled to the bottom. This flocculent, gelatinous mass covers the sand and passes into its voids. As the water is forced through it the bacteria and suspended matter are held, leaving a clear effluent to pass through. Other coagulants are used, such as the hydrate of iron, but it costs more than alum and is not so effective in removing color, although it is an excellent coagulant for removing turbidity. Physicians have made objection to the use of alum for this purpose, on the ground that any excess might pass into distribution-pipes and so be consumed by the water-users to the detriment of health. While it is possible that further experience may show that there is material ground for this objection, it has thus far not been found to be so. It is, however, essential that only the necessary amount of alum should be used and that there may be a sufficient amount of alkali to combine with the sulphuric acid. Otherwise the acidulated water may attack the iron and lead pipes and so injure the water and produce serious trouble. It can only be stated that the method and operation of these mechanical filters have thus far been sufficiently successful to avoid any of these difficulties.

[Illustration: The Jewell Filter-plant at Norristown, Penn.]

=248. Principal Parts of Mechanical Filter-plant—Coagulation and Subsidence.=—The principal parts of a complete mechanical filter-plant in the order of their succession are a solution-tank, a measuring-tank, a sedimentation-basin, and a filter. In case of great turbidity the sedimentation may be completed in two stages, the first in a settling-basin prior to receiving the coagulant, and the second in another basin subsequent to the coagulation. The tanks are usually of wood, although they may be of steel. The solution-tank is a comparatively small vessel in which the alum is dissolved. The solution is then run into the measuring-tank, from which it flows into the water at a constant rate maintained by suitable regulating apparatus. It is imperative for the successful working of the mechanical filter-plant that the coagulant be introduced to the water at a uniform rate. This rate will obviously depend upon the character of the water. The coagulating solution runs from the measuring-tank into the pipe through which the water to be filtered flows and in which it first receives the alum. The water and the coagulating solution are thus thoroughly mixed and flow into the sedimentation-basin. The subsidence which is provided for in this basin may be omitted in very clear waters which carry little solid matter, but the operation of the filter itself will be more satisfactorily accomplished if as much work as feasible is done before reaching it. The mixture must remain in this basin a sufficient length of time to allow such subsidence as can reasonably be attained.

It appears from experience in this part of the work that it is not well to introduce the coagulant too long before the water enters the filter, especially if the water be fairly clear. In the case of the presence of finely divided solid matter, however, sufficient time must be permitted for the necessary settlement. A period ranging in length from ½ hour to 6 or 8 hours may be advantageously assigned to this part of the operation, the shorter period for clear waters and the longer for very turbid waters. It has been suggested that two applications of the coagulant might be beneficial, the principal portion being given to the water before entering the sedimentation-basin and the other just before the waters enters the filter. The work of the filter, especially with turbid waters, may be much reduced by simple subsidence for a period of perhaps 24 hours before receiving the coagulant, the secondary subsidence taking place in the settling-basin in the manner already described. Duplicate solution- and measuring-tanks will be required in order that the process may be continuous while one set is out of use. In this process it is absolutely essential also that the coagulant should be of the best quality, inferior grades having been found to be unsatisfactory in their operation.

=249. Amount of Coagulant—Advantageous Effect of Alum on Organic Matter.=—The amount of sulphate of alumina will vary largely with the quality of water. In the investigation made by Mr. Fuller in connection with the Ohio River supply for the city of Cincinnati, he found that with very slight turbidity only ¾ grain was required per gallon of water, but that a high degree of turbidity required as much as 4.4 grains per gallon, with intermediate amounts for intermediate degrees of turbidity. It was estimated that these quantities would correspond to an average annual amount of about 1.6 grains per gallon. In case there should be a period of three days of subsidence preliminary to filtration, he estimated that for the greater part of the time the amount of alum would vary from 1 to 3 grains per gallon. Occasionally more and sometimes less would be required.

Alum has some specially valuable qualities in connection with this class of purification work. It combines with coloring matter, particularly that which has been acquired from contact of the water with vegetation, and precipitates it. It seems to combine also, to some extent, with the organic matter carried by the water and thus enhances the efficiency of filtration.

=250. High Heads and Rates for Rapid Filtration.=—The principal work of investigation of filtration in mechanical or pressure filters has been made for the cities of Pittsburg, Cincinnati, Louisville, and Providence, R. I. In the experimental work of those investigations rates of filtration ranging from 46 million to 170 million gallons per acre per day have been employed with essentially the same efficiency. This is a practical result of great importance, particularly if in the continued use of these filters on a large scale a satisfactorily high efficiency can be reached and maintained. It was observed that the number of bacteria in the effluent varied with that in the raw water. It was also noticed that similarly to the operation of slow sand filters the rate of filtration should not be changed suddenly, as that is likely to cause breaks in the sand and militate against continued efficiency.

In his experimental work at Cincinnati Mr. Fuller found that with fine sand an available head on the filter of 12 feet gave economical results. He also states that “high rates are more economical than low ones, and that the full head which can be economically used should be provided. Just where the economical limit of the rate of filtration is can only be determined from practical experience with a wider range of conditions than exist here, but there seem to be no indications that the capacity of a plant originally constructed on a medium rate basis (100 million to 125 million gallons per acre daily) could not readily and economically be increased, as the consumption demanded, to rates at least as high as the highest tried here (170 million gallons per acre daily), provided the full economical increase in loss of head could be obtained.”

=251. Types and General Arrangement of Mechanical Filters.=—These mechanical or pressure (by gravity) filters have until lately been constructed by companies owning patents either on the process or on the different parts of the filters. The fundamental patent, however, protecting rapid sand filters with the continuous application of a coagulant has expired and the city of Louisville, Ky., is now constructing rapid sand filters different in design from those heretofore used. The types that have been most common heretofore are the Jewell subsidence gravity filter, the Continental gravity filter, the New York sectional-wash gravity filter, and others. They all possess the main feature of accelerating the rate of filtration by pressure, either in a closed tank (rarely) with comparatively small water volume above the sand or by an open filter with sufficient head of water above the sand to accomplish the high rate desired. This latter method is that now generally used, as by it the requisite steadiness of head or pressure can be secured. The closed type is subject to objectionable sudden changes of pressure which prevent or break uniform rates of filtration. The sand is supported upon a platform with a suitable system of pipes fitted with valves or gates for the withdrawal of the filtered water, the space below the platform forming a small sedimentation-chamber. They are usually constructed in comparatively small circular units, so that one or more of a group may be withdrawn from operation for the purposes of cleaning or repairs without interfering with the operation of the others. This system of small units, gives some marked practical advantages, as housing is readily accomplished, and if necessary the plant may be easily removed from one point to another.

[Illustration: Continental Filter.]

It is obvious that with the large amount of water forced through a given area of filter-bed the sand will become clogged within a comparatively short time, requiring washing and replacing. Mr. Fuller found at Cincinnati that the periods between washings when fine sand was used in the filters ranged from 8 to 24 hours, with an average of 15, but with coarse sand the average became 20, with a range of from 6 to 36 hours. The time required for washing the sand at Cincinnati was 20 minutes for coarse or 30 minutes for fine. At Providence Mr. Weston found that the average time of washing was about 11 minutes. The cleaning is accomplished partially by stirring the sand with revolving arms, as shown in the accompanying figures, but generally by forcing the water in a reverse direction through the sand and allowing the wash-water either to run to waste or to be again purified. The filters are designed for the purpose of cleaning by the reversal of the direction of the flow of water. Latterly the sand has been cleaned by forcing compressed air at a low pressure through it and the superimposed water. The passage of the air or water upward through

the sand produces such a commotion among the grains that they rub against each other and clean themselves of the adhering material, allowing it to be carried off by the water above the sand. Both methods are much used and are satisfactorily effective for the purpose.

It was found at Cincinnati that 4 to 9 per cent, with an average of 5 per cent, of filtered water was required for washing the fine sand, and only 2 to 6 per cent, with an average of 3 per cent, for the coarse sand of the mechanical filters used in Mr. Fuller's experiments. Mr. Weston has found about the same figures in his experimental work at Providence. The wash-water need not be wasted at all if it is pumped back into the subsidence-tanks.

It has been found in some cases that the efficiency of the filters after washing is not quite normal, and that possibly 2 or 3 per cent of the water must be wasted unless it is allowed to run back into the subsidence-tanks and again pass through the filter. Under such circumstances it has required 20 to 30 minutes of operation of the filter after washing to regain its normal efficiency.

=252. Cost of Mechanical Filters.=—The cost of these mechanical filters has been found to range as high as a rate of $500,000 per acre, which is probably about ten times as much as the rate of cost for the slow sand filters. On the other hand, the efficiency of the mechanical filters may be as high as the other class, with a rate of filtration from thirty to fifty times as great, and with a cost of operation less than that of the slow sand filters. The cost of the filters per million gallons of filtered water may, therefore, be reduced to perhaps one fourth of that of the slow sand type.

=253. Relative Features of Slow and Rapid Filtration.=—It is premature, even unnecessary, to make a comparison between the slow and rapid sand filters. The former are well adapted to a large class of potable waters in which there is not too much or too finely divided solid matter and in which the coloring from organic origin is not serious. They have the advantage of requiring no chemicals and are capable of attaining a high degree of efficiency. The average rate of filtration may be taken about 3,000,000 gallons per acre per day. The rapid sand filter, on the contrary, requires the application of a coagulant, but has thirty to fifty times the capacity of the other class. It is better adapted to the removal of turbidity and color, and when properly operated it gives a high efficiency. A sufficiently extended experience has not yet, however, been attained to enable a complete statement to be made as to the entire field to which they may be adapted. They have certainly been shown to possess valuable qualities in a number of respects, and they are undoubtedly destined to play an important part in the purification of waters.

PART IV.

SOME FEATURES OF RAILROAD ENGINEERING.

CHAPTER XXI.

=254. Introductory.=—The first step toward the construction of a railroad is the location of the line, which requires as an initiative a careful ocular examination of the general vicinity of the proposed road, supplemented by simple and approximate instrumental work rapidly performed. Following this reconnaissance, as it is called, more complete surveys and examinations are made both in the field and on the maps plotted from the data of the field-work. The prosecution of this series of operations produces the final location, together with the accumulation of such maps, profiles, and other data as may be required in the construction of the road-bed, bridges, and other structures constituting the complete railroad line with its ballast and track in place ready for traffic.

The ultimate purpose of any railroad line is the transportation of passengers and freight under conditions, including those of a physical nature connected with the road as well as the rates received, leading to profitable returns. Competition or other circumstances attending the traffic of a given road will fix the maximum rates to be charged for transportation. It is the business, first, of the civil engineer so to locate and design the road and, second, of the manager so to conduct the transportation as to make the margin of profits the greatest possible. It will be the purpose of this lecture to consider in a general way only some of the features of a railroad and its operation which are related directly to civil-engineering.

[Illustration: The Royal Gorge.]

=255. Train Resistances.=—It is a fact confirmed by constant daily experience that, however nicely the machine impelling the railroad train or the tracks supporting the cars may be built, considerable frictional and other resistance is offered to the movement of the train when the latter passes over a perfectly level and straight track.

A considerable portion of the cost of transportation is expended in overcoming this resistance. When the line fails to be either level or straight other resistances of magnitude are developed; they are called the resistances of grades and curves: and it is the business of the civil engineer so to design the railroad as to reduce these two classes of resistance to an absolute minimum, in view of certain other conditions which must be concurrently maintained.

=256. Grades.=—The grade of a railroad is expressed usually in this country by the number of feet through which 100 feet of length of line rises or falls, or by some expression equivalent to that. If, for instance, the line rises 1.5 or 2 feet in 100, it is said to have an ascending grade of 1.5 or 2 per cent. Or if the line falls the same amount in the same length, it is said to have a descending grade of 1.5 or 2 per cent. It is evident that a grade which descends in one direction would be an ascending grade for trains moving in the opposite direction, so that grades favoring traffic in one direction oppose it in the other. Hence, other things being equal, that road is the most advantageous for the movement of trains which has the least grade. The grades of railroads seldom exceed 2 or 2.5 per cent, although, as will presently be shown, there are some striking exceptions to that general observation. The actual angles of inclination of railroad tracks from a horizontal line are therefore as angles very small, but their disadvantages for traffic increase rapidly.

A simple principle in mechanics shows that if the railroad train with a weight _W_ moves up a 2 per cent grade, one component of the train weight acts directly against the tractive force of the locomotive or other motive power. If _a_ is the angle of inclination of the track to a horizontal line, this opposing component will have the value _W_ sin _a_. When angles are small their sines are essentially equal to their tangents. Hence, in this case, sin _a_ would have the value .02 or ¹/■■ of the train weight. If the weight of the train were 500 tons, which is a rather light train for the present time, this opposing force would be 10 tons, or 20,000 pounds, which, as we shall see later on, is more than one half of the total tractive force of any but the heaviest locomotives built at the present day. This simple instance shows the advantage of keeping railroad grades down to the lowest practicable values.

One of the most economical freight-carrying roads in the United States is the Lake Shore and Michigan Southern of the New York Central system, running from Buffalo to Chicago. Its maximum grade is 0.4 of 1 per cent. The maximum grade of the N. Y. C. & H. R. R. R. is 0.75 of 1 per cent between New York City and Albany and between Albany and Buffalo, 1.74 per cent at Albany, 1.12 per cent at Schenectady, and 1 per cent at Batavia. Pushers or assistant locomotives are used for heavy trains at the three latter points. The maximum grade of the Pennsylvania R. R. on the famous Horseshoe Curve between Altoona and Cresson is 1.8 per cent. It is advantageous, whereever practicable, to concentrate heavy grades within a short distance, as in the case of the New York Central at Albany, and use auxiliary engines, called pushers or assistants. Some of the heaviest grades used in this country are found on the trans-continental lines where they pass the summits of the Rocky Mountains or the Sierras. In one portion of its line over a stretch of 25.4 miles the Southern Pacific R. R. rises 2674 feet with a maximum grade of 2.2 per cent; also approaching the Tehacipi Pass in California the maximum grade is about 2.4 per cent. At the Marshall Pass on the Denver & Rio Grande R. R. there is a rise of 3675 feet in 25 miles with a maximum grade of 4 per cent. The Central Pacific R. R. (now a part of the Southern Pacific system) rises 992 feet in 13 miles with a maximum grade of 2 per cent. The Northern Pacific R. R. rises at one place 1668 feet in an air-line distance of 13 miles with a maximum grade of 2.2 per cent. Probably the heaviest grade in the world on an ordinary steam railroad is that of the Calumet Mine branch of the Denver & Rio Grande R. R., which makes an elevation of 2700 feet in 7 miles on an 8 per cent grade and with 25° curves as maximum curvature. These instances are sufficient to illustrate maximum railroad grades found in the United States.

=257. Curves.=—Civil engineers in different parts of the world have rather peculiar classifications of curves. In this country the railroad curve is indicated by the number of degrees in it which subtend a chord 100 feet in length. Evidently the smaller the radius or the sharper the curvature the greater will be the number of degrees between the radii drawn from the centre of a circle to the extremities of a 100-feet chord. American civil engineers use this system for the reason that the usual tape or chain used in railroad surveying is 100 feet long. A very simple and elementary trigonometric analysis shows that under this system the radius of any curve will be equal to 50 divided by the sine of one half of the angle between the two radii drawn to the extremities of the 100-feet chord. In other words, it is equal to 50 divided by the sine of one half the degree of curvature. The application of this simple formula will give the following tabular values of the radii for the curves indicated:

Curve. Radius in Feet.

1° 5729.65 2° 2864.93 3° 1910.08 4° 1432.69 5° 1146.28 6° 955.36 7° 819.02 8° 716.78 9° 637.27 10° 573.69 12° 478.74 15° 383.06 20° 287.91

=258. Resistance of Curves and Compensation in Grades.=—Inasmuch as the resistance offered to hauling the train around a curve increases quite rapidly as the radius of curvature decreases, it is obvious that in constructing a railroad the degree of each curve should be kept as low as practicable, and that there should be no more curves than necessary. While no definite rule can be given as to such matters, curves as sharp as 10° (573.69 feet radius) should be avoided wherever practicable. It is not advisable to run trains at the highest attainable speeds around such curves, nor is it done. Inasmuch as curve resistance has considerable magnitude, as well as the resistance of grades, it is natural that wherever curves occur grades should be less than would be permissible on straight lines or, as they are called, tangents. If a maximum gradient is prescribed in the construction of a railroad, that gradient will determine the maximum weight of train which can be hauled on the straight portions or tangents of the road. If one of these grades should occur on a curve, a less weight of train could be handled by the same engine than on a tangent. Hence it is customary to reduce grades by a small amount for each degree of curvature of a curve. This operation of modifying the grades on curves so as to enable a locomotive to haul the same train around them as up the maximum grade on a tangent is called compensating the curves for grade. There is no regular rule prescribed for this purpose, because the combination may necessarily vary between rather wide limits in view of speed, condition of track, and other influencing elements. The compensation, however, has perhaps frequently been taken as lying between .03 and .05 per cent of grade for each degree of curvature. In other words, for a 5° curve the grade would be .15 to .25 per cent less than on a tangent. This compensation for grades is carefully considered in each case by civil engineers in view of experience and such data as special investigations and general railroad operation have shown to be expedient.

[Illustration: FIG. 1. GRAVEL BALLAST]

[Illustration: FIG. 2. STONE BALLAST

NEW YORK CENTRAL & HUDSON RIVER RY.]

[Illustration: FIG. 3. PENNSYLVANIA RY.]

=259. Transition Curves.=—High speeds for which modern railroads are constructed have made it necessary not only to protect road-beds, but also to make the passage from tangents to curves as easy and smooth as possible. This is accomplished by introducing between the curve and the tangent at each end what is called a “transition” curve. This is a compound curve, i.e., a curve with varying radius. At the point where the tangent or straight line ceases the radius of the transition curve is infinitely great, and it is gradually reduced to the radius of the actual curve at the point where it meets the latter. By means of such gradual change of curvature the trucks of a rapidly moving train do not suddenly pass from the tangent to the curve proper, but they pass gradually from motion in a straight line to the sharpest curvature over the transition curve. The rate of transition is fixed by the character of the curves, which have been subjected to careful analysis by civil engineers, and they can be found fully discussed in standard works on railroad location.

[Illustration: FIG. 4.—Baltimore Belt-line Tunnel, B. & O. Ry.]

=260. Road-bed, including Ties.=—Not only the high rates of speed of modern railroad trains but the great weights of locomotives and cars have demanded a remarkable degree of perfection in the construction of the road-bed and in the manufacture of rails. The favorite ballast at the present time for the best types of road-beds is generally broken stone, although gravel is used. The first requisites are a solid foundation and perfect drainage whether in cuts or fills. Figs. 1, 2, 3, and 4 show two or three types of road-bed used by the New York Central and Hudson River R. R., the Pennsylvania R. R., and a special type adopted by the B. & O. for the belt-line tunnel at Baltimore. These sections show all main dimensions and the provision made for drainage. The general depth of ballast is about 18 inches, including the drainage layer at the bottom. The total width of road-bed for a double-track line varies frequently between 24 and 25 feet, while the width of a single-track line may be found between 13 and 14 feet. In the cross-sections shown the requirements for drainage are found to be admirably met. Timber ties are almost invariably used at the present time in this country, although some experimental steel ties have been laid at various points. Fig. 5 shows the steel tie adopted for experiment on the N. Y. C. & H. R. R. R. within the city limits of New York. The time will undoubtedly come when some substitute for timber must be found, but the additional cost of steel ties at the present time does not indicate their early adoption.

[Illustration: FIG. 5.]

[Illustration: FIG. 6.]

[Illustration: Cañon of the Rio Las Animas, near Rockwood.]

=261. Mountain Locations of Railroad Lines.=—The skill of the civil engineer is sometimes severely taxed in making mountain locations of railroads. Probably no more skilful engineering work of this kind has ever been done than in the crossings of the Rocky Mountains and the Sierras in this country by trans-continental railroad lines, although more striking examples of railroad location for short distances may perhaps be found in Europe or other countries. The main problem in such

cases is the making of distance in order to attain a desired elevation without exceeding maximum grades, such as those which have already been given. Most interesting engineering expedients must sometimes be resorted to. One of the oldest of these is the switchback plan shown in Fig. 6. This is probably the simplest procedure in order to make distance in attaining elevation. The line is run up the side of a mountain at its maximum grade as far in one direction as it may be desirable to go. It then runs back on itself a short distance before being diverted so as to pass up another grade in the reverse direction. This zigzagging of alignment may obviously be made to attain any desired elevation and so overcome the summit of a mountain range. The old switchback coal road near Mauch Chunk, Pa., is one of the oldest and more famous instances of the method, which has many times been employed in other locations.

[Illustration: FIG. 7.]

A more striking method, perhaps, is that of loops by which the direction of a line or motion of a train on it is continuous. Distance is made by a judicious use of the topography of the locality so as to run the line as far up the side of the valley as practicable and then turn as much as a semicircle or more, sometimes over a bridge structure and sometimes in tunnel, so as to give further elevation by running either on the opposite side of the valley or on the same. A succession of loops or other curves suitably located will give the distance desired in order to reach the summit.

=262. The Georgetown Loop.=—Fig. 7 shows one of these spiral or loop locations on the Georgetown branch of the Union Pacific Railroad in Colorado. It is a well-known and prominent instance of railroad location of this kind. On the higher portion of this loop system included in the figure there is a viaduct on a curve which crosses the line 75 feet above the rail below it and 90 feet above the water. This location is a specimen of excellent railroad engineering. The length of line shown in the figure, including the spiral, is 8½ miles, and it cost $265,000 per mile exclusive of the bridges.

=263. Tunnel-loop Location, Rhætian Railways, Switzerland.=—In Figs. 8 and 9 are shown two portions of the Albula branch of the Rhætian Railways, Canton Graubünden, southeastern Switzerland. The line connects the valleys of the Albula and the Inn, the former being one of the branches of the Rhine and the latter of the Danube; it therefore cuts the divide between the watersheds of those two rivers. It is a 3.28-feet gauge single-track road, and is built largely for tourist traffic, as the scenic properties of the line are remarkable.

The maximum grade on this line is 3.5 per cent. Over one portion of the line 7.8 miles long one third of that distance is in tunnel and 15 per cent of it on viaducts. The radii of the centre lines of the tunnels are 460 and 394 feet, while the lengths of the tunnels range from 1591 to 2250 feet, with a maximum grade in them of 3 per cent. The weight of rails used is 50 pounds per yard on grades of 2.5 per cent or less, but for heavier grades 55-pound rails are employed. The cross-ties are of mild steel and weigh 80 pounds each except in the long Albula tunnel, where treated oak ties are used as being better adapted to the special conditions existing there. It will be observed that in each case the line rises from the left-hand portion of the figure toward the right.

[Illustration: FIG. 8.]

[Illustration: FIG. 9.]

The tunnels are represented by broken lines, and they are in every instance on circular curves. Fig. 9 represents the line running from a point on the east side of the Albula River through a heavy cut and then across the valley of the Albula into a tunnel 2250 feet long. The line then runs chiefly in cuts to a point where there are two tunnels, one over the other; indeed the line over-laps itself in loops and tunnels a number of times in that vicinity. That portion of the road shown in Fig. 8 is less remarkable than the other, although it exhibits extraordinary alignment. This example of railroad location is one of the most striking among those yet completed. It would appear to indicate that no topographical difficulties are too great to be overcome by the civil engineer in railroad location in a most rugged and precipitous country. Obviously such a line could not be economically operated for heavy freight traffic.

Railroad lines frequently lead through mountainous regions affording some of the grandest scenery in the world accessible to the travelling public. In this country the Canadian Pacific, the Northern Pacific, the Great Northern, and the Rio Grande Western

probably exhibit the most remarkable instances of this kind.

CHAPTER XXII.

=264. Railroad Signalling.=—The birth of the art of railroad signalling was probably coexistent with that of the railroad. At the very outset of the movement of railroad trains it became imperative to insure to a given train the sole use of the single track at schedule periods. Both head-to-head and rear-end collisions were liable to occur on main tracks, as well as false meetings at branches and cross-overs.

=265. The Pilot Guard.=—One of the earliest if not the earliest of systematic procedures in England to accomplish the safe use of a railroad track involved the employment of the “pilot guard” on single-track roads. The pilot was an employé whose duty it was to accompany every train over a stated section of the line. The authority to start trains was lodged in him. When it became necessary to start two or three trains from the same point and in the same direction, it was also his duty to issue to each train conductor what was called a pilot ticket, equivalent to a modern train order to run the train over the section under his control. In that case he was obliged to accompany the last train to the other end of his section, and no more trains could move over that section in the same direction until his return to his first station. As no train could pass over the section without either him or his pilot ticket, it is clear that the system could prevent head-to-head collisions, but in itself it is not sufficient to eliminate rear-end collisions. This system is still employed in Great Britain on some short branch lines.

=266. The Train-Staff.=—Another method nearly as old as the preceding is that of the train-staff, used in an improved form at the present time on some single-track roads. No train under this system can pass over any given section of the line unless it carries the staff belonging to that section, the staff being a piece of wood or metal 1 to 1¼ inches in diameter and 18 to 20 inches long. In order to cover the case of two or more trains starting in the same direction at one end of a section before running a train in the opposite direction, tickets were issued, the staff being taken by the last train. The proper operation of this method, like that of the preceding, would prevent head-to-head collisions, but is not sufficient in itself to prevent one train running into the rear of another while both are proceeding in the same direction in the same section.

=267. First Basis of Railroad Signalling.=—These and other similar systems answered fairly well the more simple requirements of early railroad operation. Strictly speaking they are not methods of signalling, although it may be said that each train is a signal in itself. With the development of railroad business it was found that other methods better adapted to a more efficient and rapid movement of trains were imperative. It was in response to the advancing requirements of the railroad business that the first approach to what is now so well known as the block system of signalling was made in 1842. An English engineer, subsequently, Sir W. F. Cooke, stated the following sound principles as to the basis of efficient railroad signalling:

“Every point of a line is a dangerous point which ought to be covered by signals. The whole distance ought to be divided into sections, and at the end as well as at the beginning of them there ought to be a signal, by means of which the entrance to the section is open to each train when we are sure that it is free. As these sections are too long to be worked by a traction rod, they ought to be worked by electricity.”

The main features of railroad signalling, as thus set forth, have continued to characterize the development of the block system from that early day to the present. The electrical application to which reference is made in the preceding quotation was that of the needle, which by its varying position could indicate either “line clear” or “line blocked.” In 1851 electric bells were used in railroad signalling on the Southeastern Railway of England. Various other developments were completed from time to time in Great Britain until the Sykes system of block signalling was patented in 1875. One of the main features of the system, and perhaps the most prominent, was the control of the track signals at the entrance end of the block by the signalman at the advance end. He exerted this control by electrically operated locks. About 1876 the Pennsylvania Railroad introduced the block system into the United States, which has since been greatly developed in a number of different forms, and its use has been widely extended over many if not most of the great railroad systems of the country. It is not only used for the movement of trains, but also for the protection of such special danger-points as switches, cross-overs, junctions, drawbridges, heavy descending grades, sharp curves, and other points needing the protection which a well-designed block system affords.

=268. Code of American Railway Association.=—The code of the American Railway Association gives the following definitions among others pertaining to the block system:

Block.—A length of track of defined limits, the use of which by trains is controlled by block signals.

Block Station.—The office from which block signals are operated.

Block Signal.—A fixed signal controlling the use of a block.

Home Block Signal.—A fixed signal at the entrance of a block to control trains in entering and using said block.

Distant Block Signal.—A fixed signal of distinctive character used in connection with a home block signal to regulate the approach thereto.

Advance Block Signal.—A fixed signal placed in advance of a home block signal to provide a supplementary block between the home block signal and the advance block signal.

Block System.—A series of consecutive blocks controlled by block signals.

Telegraph Block System.—One in which the signals are operated manually upon telegraphic information.

Controlled-Manual Block System.—One in which the signals are operated manually, and by its construction requires the co-operation of a signalman at both ends of the block to display a clear signal.

Automatic Block System.—One in which the signals are operated by electric, pneumatic, or other agency, actuated by a train or by certain conditions affecting the use of a block.

=268a. The Block.=—It is seen by these definitions that what may be called the unit in railroad signalling is the “block”; it may be of almost any length from a few hundred feet to 6 or 8 miles, or even more. On a single-track railroad it may evidently extend from one side track or passing-place to another. Over portions of lines carrying heavy traffic it may be a half-mile or less. The length of block will depend, then, upon the intensity and kind of traffic, the physical features of the line, such as curvature, grade, sidings, cross-overs, and other similar features, the location, whether in cities, towns, or open country, as well as upon other elements affecting conditions of operation which it is desirable to attain.

=269. Three Classes of Railroad Signals—The Disc.=—The signals used in railroad operation may mainly be divided into three classes: semaphores, banners, and discs. In general they may convey information by form, position, and color. The disc is used by causing it to appear and disappear before an aperture, usually a little larger than itself, in a case standing perhaps 10 or 12 feet high alongside the track, and is admirably typified in the Hall electric signal. On account of its shape, the case in which the disc is operated is frequently called the banjo, as it is quite similar in shape to that musical instrument placed in a vertical position, the key end resting on the ground.

=270. The Banner Signal.=—The banner signal is usually operated by rotation about a vertical axis, frequently in connection with switches. Its full face painted red, exposed with its plane at right angles to the track, indicates “danger” or “stop.” With its face turned parallel to the track, showing only its edge to approaching trains, a “clear” line or “safety” is indicated.

In the present development of railroad signalling the banner and disc patterns have a comparatively limited application, although, on the whole, they are largely used. The banner signal is mostly employed in the manual operation of switches, turn-outs, and cross-overs, and for other local purposes, particularly on lines of light traffic.

[Illustration: FIG. 10.—Semaphore Signals.]

=271. The Semaphore.=—The semaphore is now mainly used in connection with block signalling. Like many other appliances in railroad signalling it was first used in England, by Mr. C. H. Gregory, about 1841. Its name is derived from the combination of two Greek words signifying a sign-bearer. It consists of a post varying in height from about 3 to 35 or 40 feet, carrying an arm at its top from 3 to 5 feet long, pivoted within a foot or 18 inches of one end, the long end suitably shaped and painted and the other arranged with a lens so that when operated at night in connection with a lamp it may exhibit a properly colored light. The post of the semaphore is placed alongside the track so as to be on the right-hand side of an approaching train, the long arm rising and falling as a signal away from the track and in a plane at right angles to it. The other arm of the semaphore signal may be connected by wires or rods and light chains running over pulleys with suitable levers and weights operated either in a near-by signal cabin or by a signalman stationed near the semaphore itself; or it may be operated by electric or pneumatic power, as in many of the later installations. The semaphore may, therefore, be operated at the post or by suitable appliances at a distance.

[Illustration: Semaphore on Pennsylvania Railroad.]

=272. Colors for Signalling.=—The colors used either for painted signals for daylight exposure or for coloring lenses for night signalling are red, white, and green, as ordinarily employed in this country; red signifying “danger” or “stop,” white signifying “safety” or “clear track,” and green signifying “caution” or “proceed with train under control,” indicating that a train may go forward cautiously, expecting to find an obstruction or occupied track. In England green is largely employed to indicate “safety” or “clear track,” on the ground that a white light is so similar to any other in its vicinity that the latter may too easily be mistaken for a signal. While there is some diversity of views in this country on that point, the consensus of engineering opinion seems to favor the retention of the white for the track safety signal.

=273. Indications of the Semaphore.=—It is evident that a semaphore affords facilities of form, position, and color in its use for the purpose of signalling. The horizontal position is the most striking for the semaphore arm, as it then extends at right angles to the post and to the right or away from the track; this position is, therefore, taken to indicate “danger” or “stop.” No train may, therefore, proceed against a horizontal semaphore arm.

It might at first sight appear that the vertical position of the semaphore arm close against the post could be taken to indicate “safety” or “clear track” or “proceed,” but experience has shown that such a position may be injudicious, except under special conditions where it has lately been employed to make that indication. If the semaphore arm should be knocked or blown from the ordinary post, the engineman of an approaching train probably would not be able to detect the actual condition of things and might accept the appearance of the semaphore as indicating a clear line, thus justifying himself in proceeding at full speed, while the signalman in his cabin might have placed the signal at “danger.” A position of the semaphore arm, therefore, at an angle of 65° or 70° below the horizontal is usually taken as a safety signal. This position is in marked contrast to the horizontal arm and at the same time makes the absence of the semaphore arm impossible without immediate detection from an approaching locomotive. After dark the semaphore in a position of danger exhibits a red light through the lens in its short arm when the long arm is at the “danger” position or horizontal. Similarly, when the long arm is in the safety position a white light is exhibited through the lens in the shorter arm, so that the respective conditions of clear or obstructed track are made evident to the engineman as well by night as by day on his approach to the semaphore.

In some of the latest signal work three positions of the semaphore arm on one post, known as three-position block signalling, have been employed. In this system a special post, frequently on a signal bridge over the track, permits the vertical position of the semaphore arm to indicate “clear track,” while the diagonal or inclined position below the horizontal indicates “caution.” In the Mozier three-position signal a diagonal or inclined position above the horizontal indicates “caution” an addition to the two usual positions of “stop” and “clear.”

These are the elements, so to speak, of railroad signalling at the present day. They are combined with various appliances and in various sequences, so as to express all the varied conditions of the track structure which affect the operation of the road or the movement of trains upon it. These combinations and the appliances employed in them are more or less involved in their principal features and complicated in their details, although the main principles and salient points are simple and may easily be exhibited as to their mode of operation and general results. In this treatment of the subject it will only be possible to accomplish these general purposes without attempting to set forth the mechanical details by which the main purposes of railroad signalling are accomplished.

=274. General Character of Block System.=—It is evident from what has already been stated that the block system of signalling involves the use of fixed signals located so as to convey promptly to approaching trains certain information as to the condition of points of danger approached. Furthermore, this system of signals is designed and operated on the assumption that every point is to be considered as a danger-point until information is given that a condition of safety exists. The usual position of signals, or what may be called the normal position, is that of “danger,” and no position of “safety” is to be given to any signal except to permit a train to pass into a block whose condition of safety or clear track is absolutely assured. These are the ground principles on which the signal systems to be considered are designed and operated, although there are some conditions under which the normal signal position may be that of safety.

=275. Block Systems in Use.=—The block systems now in general use are:

The Manual, in which the signals at each end of each block are wholly controlled and operated by the signalman at each signal point.

The Controlled-Manual, in which the signals at the entrance to each block are controlled either electrically or in some other manner by the signalman at the other extremity of that block, but are operated subject to that control by the signalman at the entrance of the

block.

The Auto-Manual, in which the signals are generally operated and controlled as in the Manual or Controlled-Manual, except that they are automatically returned to the danger position as the rear car of a moving train passes them.

The Automatic, in which the operation of the signals is wholly automatic and generally by electricity, or by a combination of electric and pneumatic mechanism. In this system no signalmen are required.

The Machine, which is a controlled block system for single-track operation and in which machines operated electrically with detachable parts, as staffs, are employed in connection with other fixed signals alongside the track.

The main features of these various systems of blocking are, in respect to their signalling, the same, but the means for actuating or manipulating the signals and the conditions under which moving trains receive the necessary instructions are different. They all have the same main objects in view of improving railroad operation by enhancing both safety and facility of train movement.

“Absolute” blocking is that system of block signalling which absolutely prevents one train passing into a block until the preceding train is entirely out of it, or, in other words, until the block is absolutely clear.

“Permissive” blocking is, strictly speaking, the violation of the true block system of signalling, since under it a train may under certain precautionary conditions enter a block before the preceding train has passed out of it.

=276. Locations of Signals.=—In proceeding to locate signals along a railroad line it is imperative to recognize the preceding purposes as controlling motives. Signals must be seen readily and clearly in order to be of the greatest service to the enginemen of approaching trains, and their positions must be selected with that end in view. Locations of switches, cross-overs, junctions, and other similar track features will control the locations of the signals which are to protect them. The main or home signal in these special cases may usually be placed from 50 to 200 feet from the point which is to be governed, the so-called “distant” signal being placed about 2000 feet for level track back of the main or home signal.

=277. Home, Distant, and Advance Signals.=—A complete system of signals employed in blocking includes first of all the so-called “home” signal at each extremity of a block, then at a distance of 2000 to 2500 feet back from the home signal is placed the “distant” signal. The latter is thus approached and passed before reaching the home signal. On the other side of the “home” signal at least a maximum train length into a block about to be entered by a moving train is placed the “advance” signal. The distance of the advance signal from the home signal may be 1500 to 2500 feet. As a moving train approaches the end of a block it first meets the distant signal, the purpose of which is to indicate what the engineman may expect to find at the home signal. If the distant signal is in the danger position, he will pass it with caution and place his train under control so as to be able to stop at the home signal. If he finds the distant signal in a safety position, indicating the same position of the home signal, he may approach the latter without reducing speed, confident that the next section is clear and ready for him. The advance signal forms a kind of secondary or supplementary block into which the train, under certain conditions, may enter when the block in which it is found is obstructed, but no train may pass the advance signal unless the entire block is clear except when, under permissive working, the train proceeds with caution, expecting to find the track either obstructed or occupied. This group of three signals—the distant, the home, and the advance—taken in the order in which the moving train finds them, is located at each extremity of the block. Although the home signal is said to control the movement of trains in a block at the entrance to which it is found, as a matter of fact it appears that the advance signal in the final event holds that control.

=278. Typical Working of Auto-Controlled Manual System.=—The mode of employing these signals can be illustrated in a typical way by the diagrams, Figs, 11, 12, and 13, which exhibit in a skeleton manner Pattenall’s improved Sykes system which belongs to the Auto-Controlled Manual class. In these figures the end of block 1, the whole of blocks 2 and 3, and the beginning of block 4 are shown. Stations _A_, _B_, and _C_ indicate the extremities of blocks. The signals _S_, _S■_, and _S″_ are the home signals, while _D_, _D■_, and _D″_ indicate distant signals, and _A_, _A■_, and _A″_ advance signals. As the diagrams indicate, the stretch of double-track road is represented with east- and west-bound tracks. In order to simplify the diagrams, signals and stations are shown for one track only; they would simply be duplicated for the other track. The signal cabin is supposed to be located at each station, and at that cabin are found the levers and other appliances for working the signals operated there, the signals themselves being exposed alongside the track. In each signal cabin there is an indicator, as shown at _I_, _I■_, and _I″_. On the face of each indicator there are two slots, shown opposite the lines _E_ and _F_. In the upper of these slots appears either the word “Clear” or “Blocked.” In the lower slot appears either the word “Passed” or “On.” The significance of these words will appear

presently. On this indicator face at _P_, _P■_, and _P″_ are located electric push-buttons called plungers. The operation of the levers indicated at _L_, the counterweights _d_, and the locking detail _l_ are evident from an inspection of the figure, and need no special explanation. It is only necessary to state that the locking-device _l_ holds the bar _bc_ until it is released at the proper time, and that the counterweight may then return the lever from its extreme leftward position to that at the extreme right, at the same time placing the semaphore arm _S_ in the position of danger. It is particularly important to bear in mind this last observation. The counterweight is the feature of the system which always holds the semaphore arm in the position of danger, making that its normal position, except when it is put to safety for the passing of a train.

[Illustration: FIG. 11.]

[Illustration: FIG. 12.]

[Illustration: FIG. 13.]

If a westward train is represented in Fig. 11 at _T_ as approaching station _A_ to enter the block 2, both the distant signal _D_ and the home signal _S_ being at danger, the system is so arranged that the signalman at station _A_ cannot change those signals, i.e., to a position of safety, until the signalman at station _B_ permits him to do so. If the signalman at station _A_ desires to open block 2 for the entrance of the train _T_, he asks the signalman at station _B_ by wire to release the lock _l_ to enable him to do so. If there is no train in block 2, the signalman at station _B_ pushes the button _P′_ or "plunges" it. This raises the lock _l_ at station _A_ and the signalman immediately pulls the lever _L_ to its extreme leftward position, throwing both the signals _S_ and _D_ to the position of safety or clear, indicated by the dotted lines at _S_². At the same time the indicator _E_ at station _A_ shows the words "Clear to _B_," while the slot _F■_ at _B_ shows the words "On from _A_." The signals at stations _B_ and _C_ are supposed to be in their normal position of danger, and the indicator _E′_ at station _B_ shows the words "Blocked to _C_." The home and distant signals _S■_ and _D■_ are now at danger, but the train _T_ may enter block 2 and proceeds to do so, it being remembered that the signalman at station _A_ cannot move the lever _L_, as it has passed out of his control; not even the signalman at station _B_ can give him power to do so. The train _T_ now passes station _A_ into block 2. As the last car passes over the point _G_ its wheels strike what is called a track-treadle, an appliance having electrical connection with the lock _l_. The effect of the wheels of the last car of the train passing over the treadle at _G_ is to release lock _l_, enabling the signalman at station _A_ immediately to raise the arms _S_ and _D_ to the position of danger. It is to be observed that he cannot do this until the entire train has passed into block 2; nor, since his plunger is locked by the same treadle at _G_, can he signal "Safety" or "Clear" to the entrance of block 1. Hence no train can enter block 1 to collide with the rear end of the train just entering block 2. When the signalman at station _A_ has raised his signal _S_ to danger, it again passes out of his control, indeed out of both his control and that of the signalman at _B_, until the last car of the train passes over the treadle _G■_ at the entrance of block 3.

The train has now passed into block 2 and is approaching station _B_. The signalman at _B_ asks _C_ by wire to release the lever _L■_, and if block 3 is clear, _C_ plunges at _P″_.

_C_ then throws his lever _L■_ so as to place the home and distant signals _S■_ and _D■_ at safety. The condition of things will then be shown by Fig. 12. As soon as the last car of the train has passed over the treadle at _G■_ his lever _L■_ will be released and he can then throw the lever to the danger position, raising the home and distant signals _S■_ and _D■_ to the horizontal. After the danger position is assumed by the home signal _S■_, as well as the distant signal _D■_, he has no power over them until the signalman at station _C_ confers it on him by plunging the button _P″_.

While the train has been in block 2, the indicator _I■_ has shown "Blocked to _C_" and "Train on from _A_," but as the train passes _B_ the indicator reads "Blocked to _C_" and "Train passed from _A_," while the indicator _I″_ at _C_ reads "Blocked to _D_" and "Train on from _B_." This condition of the signals and trains is shown by Fig. 13. Also, when the last car passes over the treadle _G■_, but not till then, _B_ may permit _A_ to admit a train to enter block 2 should _A_ so desire. Finally, when the train approaches _C_, the signalman at that point asks _D_ to enable him to permit the train to enter block 4, and _C_ confers the power by plunging if that block is clear. Fig. 13 exhibits the corresponding signals at _C_.

This sequence of operations is typical of what takes place in this particular block signal system at the limits of every successive block, and differs only in details characteristic of this system from those which are performed in any other block signal system.

=279. General Results.=—It is seen first that no signalman can operate a signal until the condition in the block ahead of him is such as to make it proper for him to do so, and then he can only indicate what is necessary for the safe entrance of the train into that

block. Furthermore, immediately on the passage of the train past his home signal he must put the latter to danger or the counterweight may do it for him, the train itself when in a safe position having conferred the requisite power upon him. The signalman at the advance end of the block always knows when the train is about to enter it, for he is obliged to give his permission for that entrance. His indicator shows this result, and will continue to show it until the train passes out of the block. It is to be observed that the upper openings marked _E_ on the indicator give information of the condition of the block in advance, while the lower openings give information of the block in the rear.

It is particularly important to notice that after the signalman at the advance end of a block has “plunged” his plunger remains locked and it cannot be released until the train admitted to the block covered by the plunger has completely passed out of that block, permitting the track-treadle at the entrance to the next block to unlock the plunger. This feature makes it impossible for one train to enter a block until the preceding train has passed out of it.

If the permissive system of using a block be employed, in which the train is permitted to enter that block before a preceding train leaves it, the treadle gives no protection against a rear-end collision with the first train. In such an exigency other devices must be used or the following train must proceed cautiously, expecting to find the track occupied.

=280. Distant Signals.=—Thus far the distant signals have been treated incidentally only. They may be operated concurrently with or independently of the home signal in such a way that if danger is indicated, the distant signal gives its indication prior to that of the home signal. In this manner protection is given to the rear of a train approaching a block against the home signal set at “danger.” After the obstruction is removed and the block cleared, the home signal is set at “safety” before the distant signal is cleared.

=281. Function of Advance Signals.=—The advance signals are used when for any purpose it is desired to form a short block in a regular block. If, for instance, block 3 in Fig. 11 were obstructed by a train stopped by some failure of a locomotive detail, a train approaching station _B_ in section 2 against the home signal _S■_ set at “danger” would be obliged to stop before entering block 3. It might then be permitted to enter the latter block, to be stopped by the advance signal _A■_ set at “danger” or under instructions to pass it cautiously, expecting to find the track obstructed. It is thus seen that the advance signal creates what may be called an emergency block, and in reality finally controls the movement of trains in the block in which it is located. It would never be cleared unless the home signal were first cleared, nor would it be set at “danger” unless the home signal gave the same indication.

The preceding operation of the block system of signalling controls the movement of trains along a double-track line.

[Illustration: FIG. 14.]

=282. Signalling at a Single-track Crossing.=—A somewhat similar sequence of signal operations controls train movements at a crossing, whether single- or double-track. Fig. 14 illustrates the use of signals required for the safe movement of trains at a single-track railroad crossing, which is supposed to be that of a north-and-south line crossing obliquely an east-and-west line. Precisely the same arrangement of signals operated in the same manner would be required if the crossing were at the angle of 90°. The signal cabin is placed, as shown, as near as practicable to the actual intersection of tracks. Trains may pass in either direction on either track, but in every case they would be governed by the signals at the right-hand side of the track as seen by the engineman. There will therefore be a set of signals on both sides of each track, each set governing the movement of trains in its own direction. Each home signal may be placed about 350 feet from the actual intersection, and each distant signal 1200 to 1500 feet from the home signal, or 1550 feet to 1800 feet from the intersection. Each advance signal must be at least as far in advance of the home signal as the maximum length of train, since it may be used to stop a train, the rear car of which should completely pass the home signal. In their normal positions every home signal should be set at “danger,” carrying with them the distant signals giving the same indication. The advance signals must also indicate “danger” with the home signal. No train can then pass the crossing until the home and distant signals indicate a clear line for it, the other signals at the crossing, except possibly the advance signal, being set at “danger.” If for any reason it is desired to hold the train after it is entirely free of the crossing, the advance signal would also indicate “danger.”

It is thus seen that if the signals are properly set and obeyed, it is impossible for two trains to attempt a crossing at the same time. It is not an uncommon occurrence, however, for an engineman to run his train against the danger signal, and in order to make it impossible for the train to reach the crossing even under these circumstances a derailing device is used. This derailing arrangement is shown in Fig. 14, about 300 feet from the crossing, although it may be placed from 300 to 500 feet from that point. Its purpose is to derail any train attempting to make the crossing against the danger signal. The operation of the derail is evident from the skeleton lines of the figure. When the home signal is at danger the movable part of the derailing device is at this point

turned so as to catch the flanges of the wheels as they attempt to pass it. The train is thus thrown upon the cross-ties at such a distance from the crossing as will produce a stop before reaching it. When the home signal is at safety the derail operated with the signal is closed and the line is continuous. This combination of signals and derail coacting serves efficiently to prevent collisions at crossings, although trains may be occasionally derailed in accomplishing that end. The preceding explanations of the use of signals and derail apply to a train that may approach the crossing in either direction on either track, as is obvious from an inspection of the diagram itself.

=283. Signalling at a Double-track Crossing.=—In the case of a double-track crossing, the arrangement of signals and derails is precisely the same as for a single-track crossing, each set of signals shown in Fig. 15 covering one track. In other words, the line of single track is to take the place of each rail with its set of signals in that figure. There will be but four derails, one for each track only on the approach to the crossing. The working of the signals with the derails is precisely the same as has already been explained for the single-track crossing.

[Illustration: FIG. 15.]

[Illustration: FIG. 16.]

=284. Signalling for Double-track Junction and Cross-over.=—Fig. 16 represents a skeleton diagram of signals required for a junction of two double-track roads and a cross-over. This arrangement covers the use of switches. The location of signals and signal cabin as shown is self-explanatory, after what has already been stated in connection with single- and double-track crossings. It will be observed that the home signals for both the west-bound main and branch tracks are identical in location, and are shown by the solid double flag, the distant signal being shown by its notched end at a considerable distance back of the double home signal. It will, furthermore, be observed that at each home signal there is a derailing-switch interlocked, in the lock-and-block system presently to be explained, with the home signals operated simultaneously with them. If, therefore, an engineman attempts to run his train past a home signal set at danger, the result will be the derailment of his train, thus brought to rest before it can make any collision with another. It is obvious in this case that if the switches from the main to the branch tracks or at the extremities of the cross-over are worked independently, they must be operated directly in connection with the signals. For complete protection they should be interlocked with the signals so that it would be impossible to clear any signal without simultaneously setting the switches consistently with those signals. The diagram exhibits clearly the indications which must be made in order to effect any desired train movement at such a junction of tracks.

=285. General Observations.=—Similar arrangements of signals, derails, or switches must be made wherever switches, cross-overs, and junctions are found, the detailed variations of those signals and switches being made to meet the individual requirements of each local case. The combinations of switches and switch-signals frequently become very complicated in yards where the tracks are numerous and the combinations exceedingly varied, in order to meet the conditions created by the movement of trains into and out of the yard.

The preceding explanations are intended only to give a clear idea of the main features of signalling, in order to secure the highest degree of safety and facility in the movement of trains over a modern railroad. While they exhibit the external or apparent combinations of signals for that purpose, they do not touch in detail and scarcely in general upon the mechanical appliances found in the signal cabin and along the tracks required to accomplish the necessary signal movements. The considerations in detail of those appliances would cover extended examinations of purely mechanical, electrical, pneumatic, and electro-pneumatic combinations too involved to be set forth in any but the most extended and careful study. They have at the present time been brought to a wonderful degree of mechanical perfection and afford a field of most interesting and profitable study, into which, however, it is not possible in these general statements of the subject to enter.

[Illustration: FIG. 17.]

=286. Interlocking-machines.=—The earliest machine perfected for use in this department of railroad signalling was the Saxby and Farmer interlocking-machine, first brought out in England and subsequently introduced in this country between 1874 and 1876. This machine has been much improved since and has been widely used. Other interlocking-machines have also been devised and used in this country in connection with the most improved systems of signalling, until at the present time a high degree of mechanical excellence has been reached.

The interlocking-machine in what is called the lock-and-block system of signalling is designed to operate signals, or signals in connection with switches, derailing-points, or other dangerous track features, so as to make it impossible for a signalman to make a wrong combination, that is, a combination in which the signals will induce the engineman to run his train into danger. The signals and switches or other track details are so connected and interlocked with each other as to form certain desired combinations by the movement of designated levers in the signal cabin or tower. These combinations are predetermined in the design and connections of the appliances used, and they cannot be changed when once made except by design or by breakage of the parts; they cannot be deranged by any action of the signalman. He may delay trains by awkward or even wrong movement of levers, but he cannot actually clear his signals for the movement of a train without simultaneously giving that train a clear and safe track. As has been stated, he cannot organize an accident. Figs. 17 and 18 show banks or series of levers belonging to interlocking-machines. As is evident from these figures, the levers are numerous if the machine operates the switches and signals of a large yard, for the simple reason that a great many combinations must be made in order to meet the requirements of train movements in such a yard. The signalman, however, makes himself acquainted with the various combinations requisite for outgoing and incoming trains and the possible movements required for the shifting or hauling out of empty trains. He has before him diagrams showing in full the lever movements which must be made for the accomplishment of any or of all these movements, and he simply follows the directions of the diagrams and his instructions in the performance of his duty. He cannot derange the combinations, although he may be slow in reaching them. The locking-frame which compels him to make a clear track whenever his signals give a clear indication to the engineman lies below the lower end of the levers seen in the figures. The short arms of the levers carry tappets with notches in their edges into which fit pointed pieces of metal or dogs; the arrangement of these notches and dogs is such as to make the desired combinations and no others. It will be observed that a spring-latch handle projects from a point near the upper end of each lever where the latter is grasped in operating the machine. This spring-latch handle must be pressed close to the lever before the latter can be moved. The pressing of the spring-latch handle against the lever effects a suitable train of unlocking before which the lever cannot be moved and after which it is thrown over to the full limit and locked there. The desired combination for the movement of the train through any number of switches may require a similar movement of a number of levers, but the entire movement of that set, as required, must be completely effected before the signals are cleared, and when they are so cleared the right combination forming a clear track for the train, and that one only, is secured. These meagre and superficial statements indicate in a general way, however imperfectly, the ends attained in a modern interlocking-machine. They secure for railroad traffic as nearly as possible an absolutely safe track. They eliminate, as far as it is possible to do so, the inefficiency of human nature, the erratic, indifferent, or wilfully negligent features of human agency, and substitute therefor the certainty of efficient mechanical appliances. In some and perhaps many States grade crossings are required by statute to adopt measures that are equivalent to the most advanced lock-and-block system of signalling. So vast has become railroad traffic upon the great trunk lines of the country that it would be impossible to operate them at all without the perfected modern systems of railroad signalling. They constitute the means by which all train movements are controlled, and without such systems great modern railroads could not be operated.

[Illustration: FIG. 18.]

The swiftly moving “limited” express passenger trains, equipped with practically every luxury of modern life, speed their way so swiftly and smoothly over many hundreds of miles without the incident of an interruption, and in such a regular and matter-of-fact way, that the suggestion of an intricate system of signalling governing its movements is never thought of. Yet such a train moves not a yard over its track without the saving authority of its block signals. If the engineman were to neglect even for a mile the indication of the semaphore, he would place in fatal peril the safety of his train and of every life in it.

=287. Methods of Applying Power in Systems of Signalling.=—The mechanical appliances used in accomplishing these ends are among the most efficient in character and delicate yet certain in motive power which engineering science has yet produced. The electric circuit formed by the rails of the track plays a most important part, particularly in securing the safety of the rear of the train in making it absolutely certain whether even rear cars that may have broken away have either passed out of the block or are still in it. The electric circuit in one application or another was among the earliest means used in railroad signalling. Electric power is also used in connection with compressed air for the working of signals. Among the latest and perhaps the most advanced types of lock-and-block signalling is that which is actuated by low-pressure compressed air, the maximum pressure being 15 pounds only per square inch. The compressed air is supplied by a simple compressor, and it is communicated from the signal cabin to the most remote signal or switch by pipes and suitable cylinders fitted with pistons controlled by valves, thus effecting the final signal or switch movements. It has been successfully applied at the yard of the Grand Central Station in New York City and at many other similar points. In this connection it is interesting to observe that while the original Saxby and Farmer interlocking-machine was installed from England in this country, as has already been observed, about 1875, American engineers have within a year

reciprocated the favor by furnishing and putting in place most successfully in one of the great railroad yards of London the first low-pressure pneumatic lock-and-block system[8] found in Great Britain.

[8] By Standard Railroad Signal Company of Troy, N. Y.

=288. Train-staff Signalling.=—The lock-and-block system gives the highest degree of security attainable at the present time for double-track railroad traffic, but the simpler character of the single-track railroad business can be advantageously controlled by a somewhat simpler and less expensive system, which is a modification of the old train-staff method. It is one of the "machine" methods of signalling. The type which has been used widely in England, Australia and India, and to some extent in this country is called the Webb and Thompson train-staff machine, shown in Fig. 19. It will be observed that the machine contains ten staffs (18 to 20 inches long and 1 to 1¼ inches in diameter), but as many as fifteen are sometimes used. These staffs can be removed from the machine at one end of a section of the road at which a train is to enter, only by permission from the operator at the farther end of the section. If the station at the entrance to that section is called _A_, and the station at the farther end _X_, the following description of the operation of the instrument is given by Mr. Charles Hansel in a very concise and excellent manner:

[Illustration: FIG. 19.—Webb and Thompson Train-staff Machine.]

"When a train is ready to move from _A_ to _X_ the operator at _A_ presses down the lever which is seen at the bottom of the right-hand dial, sounding one bell at _X_, which is for the purpose of calling the attention of the operator at _X_ to the fact that _A_ desires to send a train forward. The operator at _X_ acknowledges the call by pressing the lever on his instrument, sounding a bell in the tower at _A_. The operator at _A_ then asks permission from _X_ to withdraw staff by pressing down the lever before mentioned three times, giving three rings on the bell at _X_, and immediately turns his right-hand pointer to the left, leaving it in the horizontal position pointing to the words 'For staff,' indicating that he desires operator at _X_ to release his instrument so that he can take a staff or train order from it. If there is no train or any portion of a train between _A_ and _X_, the holding down of the lever at _X_ closes the circuit in the lock magnets at _A_, which enables the operator at _A_ to withdraw a staff. As soon as this staff is removed from _A_, _A_ turns the left-hand pointer to the words 'Staff out,' and in removing this staff from the instrument _A_ the galvanometer needle which is seen in the centre of the instrument between the two dials vibrates, indicating to the operator at _X_ that _A_ has withdrawn his staff. _X_ then releases the lever which he has held down in order that _A_ might withdraw a staff and turns his left-hand indicator to 'Staff out,' and with this position of the instrument a staff cannot be withdrawn from either one.

"The first method of delivering this staff to the engineer as a train order was to place it in a staff-crane, which crane was located on the platform outside of the block station. With the staff in this position it has been found in actual practice that the engineman can pick it up while his train is running at a speed of 30 miles per hour. A second staff cannot be removed from _A_ nor a staff removed from _X_ until this staff which was taken by the engineman in going from _A_ to _X_ is placed in the staff instrument at _X_; consequently the delivering of a staff from _A_ to the engineman gives him absolute control of the section between _A_ and _X_.

"This train order staff also controls all switches leading from the main line between _A_ and _X_, for with the style of switch-stand which we have designed for the purpose the trainman cannot open the switch until he has secured the staff from the engineman and inserted it in the switch-stand, and as soon as he throws the switch-lever and opens the switch he fastens the train-staff in the switch-stand, and it cannot be removed until the switchman has closed and locked the switch for the main line. When this is done he may remove the train-staff and return it to the engineman. It will thus be seen that this train order, in the shape of a staff, gives the engineman absolute control over the section, and also insures that all switches from the main line are set properly before he can deliver the train-staff to the instrument at _X_.

"In order that the operator at _X_ may be assured that the entire train has passed his station, we may divide the staff in two and deliver one half to the engineman and the other half to the trainman on the caboose or rear end of the train, and it will be necessary for the operator at _X_ to have the two halves so that he may complete the staff in order to insert it into the staff instrument at _X_, as it is impossible to insert a portion of the staff; it must be entirely complete before it can be returned to the staff instrument."

Instead of using the entire staff as a whole or in two parts, Mr. Hansel suggests that one or more rings on the body of the staff be removed from the latter and given to the engineman or other trainman to be placed upon a corresponding staff at the extreme end of the section. This would answer the purpose, for no staff can be inserted in a machine unless all the rings are in their proper positions. These rings can be taken up by a train moving at any speed from a suitable crane at any point alongside the track.

For a rapid movement of trains on a single-track railroad under this staff system an engineman must know before he approaches the end of the section whether the staff is ready for delivery to him. In order to accomplish that purpose the usual distant and home signals may readily be employed. The distant signal would show him what to expect, so that he would approach the entrance to the section either at full speed or with his train under control according to the indication. Similarly, electric circuits may be employed in connection with the staff or rings in the control of signals which it may be desired to employ.

The electric train-staff may also be used in a permissive block system, the section of the track between stations _A_ and _X_ constituting the block. In Fig. 19, showing the machine, a horizontal arm is seen to extend across its face and to the right. This is the permissive attachment which must be operated by the special staff shown on the left half of the machine about midway of its height. If it is desired to run two or three trains or two or three sections of the same train from _A_ before admitting a train at _X_ in the opposite direction, the operator at _A_ so advises the operator at _X_. The latter then permits _A_ to remove the special staff with which the extreme right-hand end of the permissive attachment is unlocked and a tablet taken out. This tablet is equivalent to a train order and is given to the train immediately starting from _A_. A second tablet is given in a similar manner to the second section or train, and a third to the third section. The last section of train or train itself starting from _A_ takes all the remaining tablets and the special staff for insertion in the machine at _X_. In this manner head-to-head collisions are prevented when a number of trains are passing through the block in the same direction before the entrance of a train in the opposite direction. This system has been found to work satisfactorily where it has been used in this country, although its use has been quite limited. Evidently, in itself, it is not sufficient to prevent rear-end collisions in a block between trains moving in the same direction. In order to avoid such collisions where a train falls behind its schedule time or for any reason is stopped in a block, prompt use must be made of rear flagmen or other means to stop or to control the movement of the first following train.

[Illustration: FIG. 20.]

The most improved form of high-speed train-staff machine is shown in Fig. 20, as made and installed by the Union Switch and Signal Company and used by a number of the largest railroad systems of the United States. In these machines the staffs are but a few ounces in weight.

CHAPTER XXIII.

=289. Evolution of the Locomotive.=—The evolution of the steam locomotive may be called the most spectacular portion of the development of railroad engineering. The enormous engines used at the present time for hauling both heavy freight and fast passenger trains possess little in common, in respect of their principal features, with the crude machines, awkward in appearance and of little hauling capacity, which were used in the early part of the nineteenth century in the beginning of railroad operation. The primitive and ill-proportioned machine, ungainly in the highest degree, designed and built by Trevithick as far back as 1803, was a true progenitor of the modern locomotive, although the family resemblance is not at first very evident. Several such locomotive machines were designed and operated between 1800 and 1829 when Stevenson's Rocket was brought out. The water was carried in a boiler on a wagon immediately behind the engine, and the steam-cylinder in those early machines was placed almost anywhere but where it now seems to belong. The Rocket has some general features of resemblance to the machines built seventy years later, but when placed side by side it might easily be supposed that seven hundred years rather than seventy had elapsed between the two productions of the shop.

After the famous locomotive trial in which Robert Stevenson distanced his competitors, the design of the locomotive advanced rapidly, and it was but a few years later when the modern locomotive began to be accurately foreshadowed in the machines then constructed. This was true both in England and the United States.

The first steam locomotive in this country is believed to be the machine built by John Stevens at Hoboken, N. J., in 1825 and operated in 1825-27. This locomotive has practically the arrangement of boiler and cylinder which is found upon the modern contractors' engines used for pile-driving, hoisting, and similar operations. It would certainly be difficult to imagine that it had any relation to the great express and freight locomotives of the present day. The rectilinear motions of the piston were transformed into the rotary motion of the wheels by means of gearing consisting of a simple arrangement of cog-wheels. About the same time a model of an English locomotive called the Stockton and Darlington No. 1 was brought to the United States by Mr. William Strickland of Philadelphia. The next important step in American locomotive development was the construction of the locomotive "John Bull" for the Camden and Amboy Railroad Company in the English shops of Stevenson & Company in the years 1830-31. This machine has the general features, although not the large dimensions, of many modern locomotives. The cow-catcher is a little more elaborate in

design and far-reaching in its proportions than the similar appendage of the present day, but the general arrangement of the fire-box and boiler, the steam-cylinders, the driving-wheels and smoke-stack is quite similar to a modern American locomotive. This machine, “John Bull,” and train made the trip from New York City to Chicago and return under its own steam in 1893. It was one of the prominent features of the World’s Columbian Exposition. It rests in the National Museum at Washington, where it is one of the most interesting early remains of mechanical engineering in this country. One of the cars used in this train was the original used on the Camden and Amboy Road about 1836. Its body was used as a chicken-coop at South Amboy, N. J., for many years, and was rescued from this condition of degradation for the purpose of the Exposition trip in 1893. The original driving-wheels had locust spokes and felloes, the hubs and tires being of iron.

The locomotive “George Washington” was built, as a considerable number have been since, with one driving-axle, and was designed to be used on heavy grades. This machine was built by William Norris & Sons of Philadelphia, who were the progenitors of the present great establishment of the Baldwin Locomotive Works. While the development of the locomotive was subjected to many vicissitudes in principles, general arrangement, and size in order to meet the varying requirements of different roads as well as the fancies or more rational ideas of the designers, its advance was rapid. As early as 1846 we find practically the modern consolidation type, followed in 1851 by the ordinary eight-wheel engine of which thousands have been constructed within the past fifty years. The first Mogul built by the Baldwin Locomotive Works was almost if not quite as early in the field. Both these types of machines carry the principal portion of their weight upon the driving-wheels and were calculated to yield a high tractive capacity, especially as the weights of the engines increased. The weight of the little “John Bull” was but 22,425 pounds, while that of the great modern machine may be as much as 267,800 pounds, with 53,500 pounds on a single driving-axle.

=290. Increase of Locomotive Weight and Rate of Combustion of Fuel.=—The development of railroad business in the United States has been so rapid as to create rigorous exactions of every feature of a locomotive calculated to increase its tractive force. Any enhancement of train-load without increasing the costs of the train force or other cost of movement will obviously lead to economy in transportation. In order that the locomotive may yield the correspondingly augmented tractive force the weight resting upon the drivers must be increased, which means a greater machine and at the same time higher working pressures of steam. This demands greater boiler capacity and strength and a proportionately increased rate of combustion, so as to move the locomotive and train by the stored-up energy of the fuel transformed in the engine through steam pressure. The higher that pressure the greater the amount of energy stored up in a unit of weight of the steam and the greater will be the capacity of a given amount of water to perform the work of hauling a train. The greater the weight of train moved and the greater its speed the more energy must be supplied by the steam, and, again, that can only be done with a correspondingly greater consumption of fuel. In the early days of the small and crude machines to which allusion has already been made the simplest fuel was sufficiently effective. As the duties performed by the locomotive became more intense a higher grade of fuel, i.e., one in which a greater amount of heat energy is stored per unit of weight, was required. Both anthracite and bituminous coal have admirably filled these requirements. The movement of a great modern locomotive and its train at an average rate of 30 to 60 miles per hour requires the combustion of fuel at a high rate and the rapid evaporation of steam at pressures of 180 to 225 or more pounds per square inch. The consumption of coal by such a locomotive may reach 100 pounds per minute, and two barrels of water may be evaporated in the same time. This latter rate would require over a gallon of water per second to be ejected through the stack as exhaust steam. Some of the most marked improvements in locomotive practice have been made practically within the past six or seven years in order to meet these exacting requirements.

While the operations of locomotives will obviously depend largely upon quality of fuel, speed, and other conditions, the investigations of Prof. W. F. M. Goss and others appear to indicate that 12 to 14 pounds of water per hour may be evaporated by a good locomotive boiler per square foot of heating surface, and that 25 to 30 pounds of steam will be required per indicated horse-power per hour.

=291. Principal Parts of a Modern Locomotive.=—The principal features of a modern locomotive are the boiler with the smoke-stack placed on the front end and the fire-box or furnace at the rear, the tubes, about 2 inches in diameter, through which the hot gases of combustion pass from the furnace to the smoke-stack, the steam-cylinders with their fittings of valves and valve movements, and the driving-wheels. These features must all be designed more or less in reference to each other, and whatever improvements have been made are indicated almost entirely by the relative or absolute dimensions of those main features. The boiler must be of sufficient size so that the water contained in it may afford a free steam production, requiring in turn a corresponding furnace capacity with the resulting heating surface. The latter is that aggregate surface of the interior chambers of the boiler through which the heat produced by combustion finds its way to the water evaporated in steam; it is composed almost

entirely of the surfaces of the steel plates of the fire-box and of the numerous tubes running through the boiler and parallel to its centre, exposed to the hot gases of combustion and in contact with the water on the opposite sides of those plates. Evidently an increase in size of the fire-box with the correspondingly increased combustion will furnish a proportionally larger amount of steam at the desired high pressure, but an increase in the size of the fire-box is limited both in length and in width. It is found that it is essentially impracticable for a fireman to serve a fire-box more than about 10 feet in length. The maximum width of the locomotive limits the width of the fire-box.

[Illustration: FIG. 21.]

=292. The Wootten Fire-box and Boiler.=—As the demand arose for an enlarged furnace the width of the latter was restricted by the width between the driving-wheel tires, less than 4 feet 6 inches. That difficulty was overcome by what is known as the Wootten fire-box, which was brought out by John E. Wootten of the Philadelphia and Reading Railroad about 1877, and has since been developed and greatly improved by others. The Wootten boiler with its sloping top and great width extending out over the rear driving-wheels presented a rather curious appearance and was a distinct departure in locomotive boiler design. Fig. 21 shows an elevation and two sections of the original Wootten type of boiler. It will be noticed that in front of the fire-box there is a combustion-chamber of considerable length, 2½ to 3 feet long. This boiler was first designed to burn the poorer grades of fuel, such as coal-slack, in which the combustion-chamber to complete the combustion of the fuel was thought essential. By Wootten's device, i.e., extending the boiler out over the driving-wheels, a much greater width of fire-box was secured, but the height of the locomotive was considerably increased. It cannot be definitely stated just how high the centre of the locomotive boiler may be placed above the track without prejudice to safety in running at high speeds, but it has not generally been thought best to lift that centre more than about 9½ feet above the tops of rails, and this matter has been held clearly in view in the development of the wide fire-box type of locomotive boilers.

Like every other new form of machine, the Wootten boiler developed some weak features, although there was no disappointment in its steaming capacity. It will be noticed in the figure that the plates forming that part of the boiler over the fire-box show abrupt changes in curvature which induced ruptures of the stay-bolts and resulted in other weaknesses. This boiler passed through various stages of development, till at the present time Figs. 22 and 23 show its most advanced form, which is satisfactory in almost or quite every detail. The sudden changes in direction of the plates in the first Wootten example have been displaced by more gradual and easy shapes. Indeed there are few features other than those which characterize simple and easy boiler construction. The enormous grate area is evident from the horizontal dimensions of the fire-box, which are about 120 inches in length by about 106 inches in breadth. The boiler has over 4000 square feet of heating surface and carries about 200 pounds per square inch pressure of steam. The combustion-chamber in front of the fire-box has been reduced to a length of about 6 inches, just enough for the protection of the expanded ends of the tubes. The barrel of the boiler in front of the fire-box has a diameter of 80 inches and a length of about 15 feet. The grate area is not far from 100 square feet. The improvements which have culminated in the production of this boiler are due largely to Mr. Samuel Higgins of the Lehigh Valley Road.

[Illustration: FIG. 22.]

[Illustration: FIG. 23.]

=293. Locomotives with Wootten Boilers.=—Fig. 24 exhibits a consolidation freight locomotive of the Lehigh Valley Railroad, having the boiler shown in Figs. 22 and 23. This machine is one of the most efficient and powerful locomotives produced at the present time. The locomotive shown in Fig. 25 has a record. It is one used on the fast Reading express service between Philadelphia and Atlantic City during the season of the latter resort. It has run one of the fastest schedule trains in the world and has attracted attention in this country and abroad. Its type is called the Atlantic and, as the view shows, it is fitted with the Wootten improved type of boiler. It will be noticed that the wide fire-box does not reach out over the rear drivers, but over the small trailing-wheels immediately behind them. This is a feature of wide locomotive fire-box practice at the present time to which recourse is frequently had. There is no special significance attached to the presence of the small trailing-wheels except as a support for the rear end of the boiler, their diameters being small enough to allow the extension of the fire-box over them without unduly elevating the centre of the boiler.

[Illustration: FIG. 24.]

The cylinders of these and many other locomotives are known as the Vauclain compound. In other words, it is a compound locomotive, there being two cylinders, one immediately over the other, on each side. The diameter of the upper cylinder is much

less than that of the lower. The steam is first admitted into the small upper cylinder and after doing its work there passes into the lower or larger cylinder, where it does its work a second time with greater expansion. By means of this compound or double-cylinder use of the steam a higher rate of expansion is secured and a more uniform pull is exerted upon the train, the first generally contributing to a more economical employment of the steam, which in turn means a less amount of fuel burned for a given amount of tractive work performed.

[Illustration: FIG. 25.]

In the early part of November, 1901, an engine of this type hauling a train composed of five cars and weighing 235 tons made a run of 55.5 miles between Philadelphia and Atlantic City at the rate of 71.6 miles per hour, the fastest single mile being made at a rate of a little less than 86 miles per hour.

The power being developed by these engines runs as high as 1400 H.P. at high speeds and 2000 H.P. at the lower speeds of freight trains.

The chief economic advantage of these wide fire-box machines lies in the fact that very indifferent grades of fuel may be consumed. Indeed there are cases where fuel so poor as to be unmarketable has been used most satisfactorily. With a narrow and small fire-box a desired high rate of combustion sometimes demands a draft strong enough to raise the fuel over the grate-bars. This difficulty is avoided in the large fire-box, where sufficient combustion for rapid steaming is produced with less intensity of blast.

=294. Recent Improvements in Locomotive Design.=—Concurrently with the development of the Wootten type of boiler, other wide fire-box types have been brought to a high state of excellence. In reality general locomotive progress within the past few years has been summed up by Mr. F. J. Cole as follows:

(_a_) The general introduction of the wide fire-box for burning bituminous coal.

(_b_) The use of flues of largely increased length.

(_c_) The improvements in the design of piston-valves and their introduction into general use.

(_d_) The recent progress made in the use of tandem compound cylinders.

[Illustration: FIG. 26.]

The piston-valve, to which reference is made, is a valve in the shape of two pistons connected by an enlarged stem or pipe the entire length of the double piston, the arrangement depending upon the length of steam-cylinder or stroke; it may be 31 or 32 inches. This piston-valve is placed between the steam-cylinder and the boiler, and is so moved by eccentrics attached to the driving-wheel axles through the medium of rocking levers and valve-stems as to admit steam to the cylinder at the beginning of the stroke and allow it to escape after the stroke is completed. Fig. 26 shows a section through the centre of one of these piston-valves. It will be noticed that the live steam is admitted around a central portion of the valve, and that the steam escapes through the exhaust-passages at each end of the piston-valve. This type of valve is advantageous with high steam pressures for the reason that its “blast,” i.e., the steam pressure, does not press it against its bearings as is the case with the old type of slide-valve, the wear of which with modern high steam pressures would be excessive, although under more recent slide-valve design this objection does not hold.

[Illustration: FIG. 27.]

=295. Compound Locomotives with Tandem Cylinders.=—The tandem compound locomotive, as recently built, is a locomotive in which the high-pressure cylinder is placed immediately in front of the low-pressure cylinder and in line with it. In the Vauclain type it is necessary to have a piston-rod for each of the two cylinders, one above the other, each taking hold of the same cross-head. In the tandem arrangement with the two cylinders each in line, but one piston-rod is required. An example of a locomotive with this tandem arrangement of compound cylinders will be shown farther on.

[Illustration: FIG. 28.]

Figs. 27 and 28 show two sections, one transverse and one longitudinal, of a type of large fire-box boiler built by the American Locomotive Works at Schenectady. The diameter of the barrel of the boiler in front of the fire-box is about 5 feet 8 inches, while the clear greatest width of the fire-box is 5 feet 4½ inches. The length of the latter is 8 feet 7 inches, making a total grate area in this

particular instance of over 45 square feet. There are 338 2-inch tubes, each 16 feet in length. The total length over all of the boiler is 31 feet ½ inch. The result of such a design is an arrangement by which a large grate area is secured and a corresponding high rate of combustion without a too violent draft. In designing locomotive boilers for bituminous coal one square foot of grate area is sometimes provided for each 60 to 70 square feet of heating surface in the tubes.

[Illustration: FIG. 29.]

=296. Evaporative Efficiency of Different Rates of Combustion.=—In the development of this particular class of locomotive boilers it is to be remembered that as a rule the highest rates of combustion frequently mean a decreased evaporation of water at boiler pressure per pound of fuel. Modern locomotives may burn over 200 pounds of coal per square foot of grate area per hour, and in doing so the evaporation may be less than 5 pounds of water per pound of fuel. On the other hand, when the coal burned does not exceed 50 pounds per square foot of grate area per hour, as much as 8 pounds of water may be evaporated for each pound of coal. It is judicious, therefore, to have large grate area, other things being equal, in order that the highest attainable efficiency in evaporation may be reached.

=296a. Tractive Force of a Locomotive.=—The tractive force of a locomotive arises from the fact that one solid body cannot be moved over another, however smooth the surface of contact may be, without developing the force called resistance of friction. This resistance is measured by what is called the coefficient of friction, determined only by experiment. The resistance of friction and this coefficient will depend both upon the degree of smoothness of the surface of contact and on its character. If surfaces are lubricated, as in the moving parts of machinery, the force of friction is very much decreased, but in the absence of that lubricant it will have a much higher value. The coefficient of friction is a ratio which denotes the part of the weight of the body moved which must be applied as a force to that body in order to put it in motion against the resistance of friction. In the case of lubricated surfaces this ratio may be as small as a few hundredths. In the case of locomotive driving-wheels and the track on which they rest this value is usually taken at .2 to .25.

There are times when it is desirable to increase the resistance of friction between locomotive drivers and the rails. For this purpose a simple device, called the sand-box, is frequently placed on the top of a locomotive boiler with pipes running down from it so as to discharge the sand on the rails immediately in front of the drivers. The sand is crushed under the wheels and offers an increased resistance to their slipping.

The tractive force of a locomotive may also be computed from the pressure of steam against the pistons in the steam-cylinders. If the indicated horse-power in the cylinder be represented by H.P., and if all frictional or other resistance between the cylinder and the draw-bar be neglected, the following equality will hold:

Draw-bar pull × speed of train in miles } per hour × 5280 } = H.P. × 33,000 × 60.

If _S_ = speed in miles per hour, and if _T_ = draw-bar pull, then the preceding equality gives

375 × H.P. _T_ = ----------. _S_

This value of the “pull” must be diminished by the friction of the locomotive as a machine, by the rolling resistance of the trucks and tender, and by the atmospheric resistance of the locomotive as the head of the train. Prof. Goss proposes the following approximate values for these resistances in a paper read before the New England Railroad Club in December, 1901.

A number of tests have shown that a steam pressure of 3.8 pounds per square inch on the piston is required to overcome the machine friction of the locomotive. Hence if _d_ is the diameter of the piston in inches, _L_ the piston-stroke in feet, and _D_ the diameter of driver in feet, while _f_ is that part of the draw-bar pull required to overcome machine friction, the following equation will hold:

π_d_ ² _f_.π_D_ = 3.8 -----× 2_L_ × 2. 4

d²L ∴ _f_ = 3.8 ------. _D_

Again, if _W_ be the rolling load in tons on tender and trucks (excluding that on drivers), and if _r_ be that part of the draw-bar pull required to overcome the rolling resistance due to _W_, then experience indicates that approximately, in pounds,

(_S_) _r_ = (2 + ---)_W_. (6)

As before, _S_ is the speed in miles per hour.

Finally, if _h_ be that part of the draw-bar pull in pounds required to overcome the head resistance (atmospheric) of the locomotive, there may be written approximately

_h_ = .11_S_².

The actual draw-bar pull in pounds available for moving the train will then be

375 H.P. _d_²_L (S_) _t = T - f - r - h_ = -------- - 3.8------ - _W_(2 + ----) - .11_S_². _S D_ (6)

The maximum value of _t_ should be taken as one fourth the greatest weight on drivers.

If _H_ is the total heating surface in square feet, and if 12 pounds of water be evaporated per square foot per hour, while 28 pounds of steam are required per horse-power per hour, then

12_H_ 375H.P. 161_H_ H.P. = ----- and -------- = ------. 28 _S S_

Hence

161_H d²L_ (_S_) _t_ = ----- - 3.8----- - _W_(2 + ----) - .11_S²_. _S D_ (6)

The actual draw-bar pull in pounds may then be computed by this formula.

Some recent tests of actual trains (both heavy and light) on the N. Y. C. & H. R. R. R. between Mott Haven Junction and the Grand Central Station, New York City, a distance of 5.3 miles, by M. Bion J. Arnold, by means of a dynamometer-car, gave the actual average draw-bar pull per ton of 2000 pounds as ranging from 12 to 25 pounds going in one direction and 12.1 to 24 pounds in the opposite direction. There were eight tests in each direction, and the greatest speed did not exceed 30 miles per hour.

As the diameter of the driver appears in the preceding formulæ, it may be well to state that an approximate rule for that diameter is to make it as many inches as the desired maximum speed in miles per hour, i.e., 70 inches for 70 miles, or 80 inches for 80 miles, per hour.

=297. Central Atlantic Type of Locomotive.=—Fig. 29 represents what is termed the Central Atlantic type (single cylinder) of engine, which is used for hauling most of the fast passenger trains on the New York Central and Hudson River Railroad. The characteristics of boiler and fire-box are such as are shown in Figs. 27 and 28.

The cylinders are 21 inches internal diameter, and the stroke is 26 inches. The total grate area is 50 square feet, and the total heating surface 3500 square feet. The total weight of the locomotive is 176,000 pounds, with 95,000 on the drivers. It will be observed that the total weight of locomotive per square foot of heating surface is scarcely more than 650 pounds, which is a low value. The boiler pressure carried may be 200 pounds per square inch or more. The tractive force of this locomotive may be taken at 24,700 pounds. There is supplied to these engines, among others, what is called a traction-increasing device. This traction-increaser is nothing more nor less than a compressed-air cylinder secured to the boiler, so that as its piston is pressed outward, i.e., downward, it carries with it a lever, the fulcrum of which is on the equalizing-lever of the locomotive frame, the other or short end of the lever being attached to the main bar of the frame itself. This operation redistributes the boiler-load on the frame, so as to increase that portion which is carried by the drivers. This has been found to be a convenient device in starting trains and on up grades. In the present instance the traction-increaser may be operated so as to increase the load on the drivers by about 12,000 pounds. It is not supposed to be used except when needed under the circumstances indicated.

[Illustration: FIG. 30.]

A number of indicator-cards taken from the steam-cylinders of these engines hauling the Empire State Express and other fast passenger trains on the Hudson River Division of the N. Y. C. & H. R. R. R., show that with a train weighing about 208 tons while running at a speed of 75 miles per hour 1323 H.P. was developed. Fig. 30 shows these indicator diagrams. With a train weighing 685 tons 1452 H.P. was indicated at a speed of 63 miles per hour.

=298. Consolidation Engine, N. Y. C. & H. R. R. R.=—One of the heaviest wide fire-box compound consolidation engines recently built for the New York Central freight service is shown in Fig. 31. It will be noticed that there is but one cylinder on each side of the locomotive, and that they are of different diameters. One of these cylinders, 23 inches inside diameter, is a high-pressure cylinder,

and the other, 35 inches inside diameter, is a low-pressure cylinder, the stroke in each case being 34 inches. The total grate area is 50.3 square feet, the fire-box being 8 feet long by 6 feet 3 inches wide. The total heating surface is 3480 square feet. The diameter of the barrel of the boiler at the front end is 72 inches, and the diameter of the drivers 63 inches. The pressure of steam in the boiler is 210 pounds per square inch. The total weight of the locomotive is 194,000 pounds, of which 167,000 rests upon the drivers. These engines afford a maximum tractive force of 37,900 pounds. This engine is typical of those used for the New York Central freight service. They have hauled trains weighing nearly 2200 tons over the New York Central road.

[Illustration: FIG. 31.]

=299. P., B. & L. E. Consolidation.=—The consolidation locomotive shown in Fig. 32 is a remarkable one in that it was for a time the heaviest constructed, but its weight has since been exceeded by at least two of the Decapod type built for the Sante Fé company. It was built at the Pittsburg works of the American Locomotive Company for the Pittsburg, Bessemer and Lake Erie Railroad to haul heavy trains of iron ore. The total weight is 250,300 pounds, of which the remarkable proportion of 225,200 is carried by the drivers. The tender carries 7500 gallons of water, and the weight of it when loaded is 141,100 pounds, so that the total weight of engine and tender is 391,400 pounds. The average weight of engine and tender therefore approaches 7000 pounds per lineal foot. This is not a compound locomotive, but each cylinder has 24 inches inside diameter and 32 inches stroke, the diameter of the driving-wheels being 54 inches. The boiler carries a pressure of 220 pounds, and the tractive force of the locomotive is 63,000 pounds.

[Illustration: FIG. 32.]

A noticeable feature of this design, and one which does not agree with modern views prompting the design of wide fire-boxes, is its great length of 11 feet and its small width of 3 feet 4¼ inches. There are in the boiler 406 2¼-inch tubes, each 15 feet long, the total heating surface being 3805 square feet.

=300. L. S. & M. S. Fast Passenger Engine.=—The locomotive shown in Fig. 33 is also a remarkable one in some of its features, chief among which is the 19 feet length of tubes. It was built at the Brooks works of the American Locomotive Company for the Lake Shore and Michigan Southern Railroad. The total weight of engine is 174,500 pounds, of which 130,000 pounds rests upon the drivers. The rear truck carries 23,000 pounds and the front truck 21,500 pounds. This is not a compound engine. The cylinders have each an inside diameter of 20½ inches, and 28 inches stroke. As this locomotive is for fast passenger traffic, the driving-wheels are each 80 inches in diameter, and the driving-wheel base is 14 feet. The fire-box is 85 × 84 inches, giving a grate area of 48½ square feet and a total heating surface of 3343 square feet. There are 285 2¼-inch flues, each 19 feet long. The tender carries 6000 gallons of water. Cast and compressed steel were used in this design to the greatest possible extent, and the result is shown in that the weight divided by the square feet of heating surface is 52.18 pounds.

[Illustration: FIG. 33.]

=301. Northern Pacific Tandem Compound Locomotive.=—The diagram shown in Fig. 34 exhibits the outlines and main features of a tandem compound locomotive to which allusion has already been made. It was built at Schenectady, New York, in 1900, for the Northern Pacific Railroad, and was intended for heavy service on the mining portions of that line.

The diameters of the high- and low-pressure cylinders are respectively each 15 and 28 inches, with a stroke of 34 inches, while the boiler pressure is 225 pounds per square inch. The total weight of the machine is 195,000 pounds and the weight on the drivers 170,000 pounds, the diameter of the drivers being 55 inches. As the figure shows, it belongs to the consolidation type. The fire-box is 10 feet long by 3.5 feet wide, giving a grate area of 35 square feet, with which is found a total heating surface of 3080 square feet. There are 388 2-inch tubes, each 14 feet 2 inches long. These engines are among the earliest compound-tandem type and have been very successful. Other locomotives of practically the same general type have been fitted with a wide fire-box, 8 feet 4 inches long by 6 feet 3 inches wide, with the grate area thus increased to 52.3 square feet.

[Illustration: FIG. 34.]

=302. Union Pacific Vauclain Compound Locomotive.=—The next example of modern locomotive is the Vauclain compound type used on the Union Pacific Railroad. It is a ten-wheel passenger engine and one of a large number in use. The weight on the drivers is 142,000 pounds, and the total weight of the locomotive is about 185,000 pounds. The high-pressure cylinder has an inside diameter of 15½ inches, while the low-pressure cylinder has a diameter of 26 inches. The stroke is 28 inches and the diameter of the driving-wheels 79 inches. On the Union Pacific Railroad the diameter of the driving-wheel varies somewhat with the grades of the divisions on which the engines run.

[Illustration: FIG. 35.]

In some portions of the country, as in Southern California, oil has come into quite extended use for locomotive fuel.

=303. Southern Pacific Mogul with Vanderbilt Boiler.=—The locomotive shown in Fig. 36 belongs to the Mogul type, having three pairs of driving-wheels and one pair of pilots. It is fitted with the Vanderbilt boiler adapted to the use of oil fuel. The locomotives of which this is an example were built for the Southern Pacific Company, and they have performed their work in a highly satisfactory manner. They are not particularly large locomotives as those matters go at the present day, as they carry about 135,000 pounds on the drivers and 22,000 pounds on the truck, giving a total weight of 157,000 pounds. The characteristic feature of the machine is its adaptation to the burning of oil, which requires practically no labor in firing, although the services of a fireman must still be retained.

[Illustration: FIG. 36.]

=304. The “Soo” Decapod Locomotive.=—It has been seen that the results of Trevethick’s early efforts was a crude and simple machine, with what might be termed, in courtesy to that early attempt, a single pair of drivers. Subsequently, as locomotive evolution took place, two pairs of drivers coupled with the horizontal connecting-rod were employed. Then the Mogul with the three pairs of coupled drivers was used, and at or about the same time the consolidation type with four pairs of coupled drivers was found adapted in a high degree to the hauling of great freight trains. The last evolution in driving-wheel arrangement is exhibited in Fig. 37. It belongs to what is called the Decapod type. As a matter of fact, five pairs of coupled driving-wheels have been occasionally used for a considerable number of years, but this engine is the Decapod brought up to the highest point of modern excellence. As shown, it uses steam by the Vauclain compound system, the small or high-pressure cylinder being underneath the low-pressure cylinder. They have been built by the Baldwin Locomotive Works for the Minneapolis, St. Paul and Sault Ste. Marie Railroad Company, on what is called the “Soo Line.” It has given so much satisfaction that more of this type but of greater weight are being built for the same company. This engine was limited to a total weight of 215,000 pounds, with 190,000 pounds on the drivers.

[Illustration: FIG. 37.]

[Illustration: FIG. 38.]

[Illustration: FIG. 39.]

[Illustration: FIG. 40.]

=305. The A., T. & S. F. Decapod, the Heaviest Locomotive yet Built.=—The heaviest locomotive yet constructed, consequently occupying the primacy in weight, is that shown in Fig. 38. It is a Decapod operated with others of its type by the A., T. & S. F. Company near Bakersfield, California. It is a tandem compound coal-burner, as shown by the illustration, the high-pressure cylinder being in front of the low-pressure. The dimensions of cylinders are 19 and 32 × 32 inches stroke, and the driving-wheels are 57 inches in diameter. The total height from the top of stack down to the rail is 15 feet 6 inches, while the height of the centre of the boiler above the rails is 9 feet 10 inches. Figs. 39 and 40 show some of the main boiler and fire-box dimensions. There are 463 2¼-inch tubes, each 19 feet long. The total heating surface is 5390 square feet, about one eighth of an acre, the length of the fire-box being 108 inches and the width 78 inches. The heating surface in the tubes is 5156 square feet, and in the fire-box 210.3 square feet; the grate surface having an area of 58.5 square feet. The boiler is designed to carry a working pressure of 225 pounds per square inch, the boiler-plates being ¹■/■■ inch, ■/■■ inch, and ■ inch thick, according to location. As shown by the illustrations, the boiler is what is termed an extended wagon-top with wide fire-box. The total weight of the locomotive itself is 267,800 pounds, while the weight on the driving-wheels is 237,800 pounds, making 47,560 pounds on each axle. The tractive force of this locomotive is estimated to be over 62,000 pounds.

=306. Comparison of Some of the Heaviest Locomotives in Use.=—The following table gives a comparison of the heaviest locomotives thus far built, as taken from the _Railroad Gazette_ for January 31, 1902, revised to September 1, 1902.

COMPARISON OF HEAVIEST LOCOMOTIVES.

---------- | Atchison, | Pittsburg, | Union | Topeka | Bessemer & | Railroad. | & Santa Fé. | Lake Erie. | ---------- Name of builder | Baldwin | Pittsburg | Pittsburg Size of cylinders |19 & 32 × 32 in.|24 × 32 in. |23 × 32 in. These instances of modern locomotive construction are impressive, especially when considered in contrast with the type of engine in use not more than fifty years ago. They indicate an almost incredible advance in railroad transportation, and they account for the fact that a bushel of wheat can be brought overland at the present time from Chicago to New York City, a distance of 900 miles, for about one third of the lowest charge for delivering a valise from the Grand Central Station in the city of New York to a residence within a mile of it.

PART V.

THE NICARAGUA ROUTE FOR A SHIP-CANAL.

=307. Feasibility of Nicaragua Route.=—The feasibility of a ship-canal between the two oceans across Nicaragua has been recognized almost since the discovery of Lake Nicaragua in 1522 by Gil Gonzales de Avila, who was sent out from Spain to succeed Balboa, after the execution of the latter by Pedro Arias de Avila at Acla on the Isthmus of Panama.

=308. Discovery of Lake Nicaragua.=—Gil Gonzales set sail from the Bay of Panama in January of that year northward along the Pacific coast as far as the Gulf of Fonseca. He landed there and proceeded to explore the country with one hundred men, and found what he considered a great inland sea, as we now know, about 14 miles from the Pacific Ocean at the place of least separation. The country was inhabited, and he found a native chief called Nicarao, who was settled with his people at or near the site of the present city of Rivas. As he found it a goodly country, fertile and abounding in precious metals, he immediately proceeded to take possession of it for his sovereign, but the Spanish explorer was sufficiently gracious to the friendly chief to name Lake Nicaragua after him. From that time the part of Nicaragua in the vicinity of the lake received much attention, and the Spaniards made conquest of it without delay. Among those who were the earliest visitors was a Captain Diego Machuca, who, with two hundred men under his command, explored Lake Nicaragua in 1529 and constructed boats on it, a brigantine among them. He seems to have been the first one who entered and sailed down the Desaguadero River, now called the San Juan, and one of the rapids in the upper portion of the river now bears his name. He pursued his course into the Caribbean Sea and sailed eastward to the Isthmus of Panama.

[Illustration: Map of American Isthmus, showing Proposed Canal Routes.]

=309. Early Maritime Commerce with Lake Nicaragua.=—Subsequently sea-going vessels passed through the San Juan River in both directions and maintained a maritime trade of some magnitude between the shores of Lake Nicaragua and Spain. Obviously these vessels must have been rather small for ocean-going craft, unless there was more water in the San Juan River in those early days than at present. There are some obscure traditions of earthquakes having disturbed the bed of the river and made its passage more difficult by reducing the depth of water in some of the rapids; but these reports are little more than traditionary and lack authoritative confirmation. It is certain, however, that the marine traffic, to which reference has been made, was maintained for a long period of years, its greatest activity existing at about the beginning of the seventeenth century. It was in connection with this traffic probably that the city of Granada at the northwestern extremity of the lake was established, perhaps before 1530.

=310. Early Examination of Nicaragua Route.=—Although the apparently easy connection between the Caribbean Sea and Lake Nicaragua, together with the proximity of the latter to the Pacific coast, at once indicated the possibility of a feasible water communication between the two oceans, probably no systematic investigation to determine a definite canal line was made until that undertaken by Manuel Galisteo in 1779 under the instruction of Charles III., who was then on the throne of Spain. Galisteo made a report in 1781 that Lake Nicaragua was 134 feet higher than the Pacific Ocean, and that high mountains intervened between the lake and the ocean, making it impracticable to establish a water communication between the two. In spite of the discouragement of this report a company was subsequently formed under the patronage of the crown to construct a canal from Lake Nicaragua along the Sanoa River to the Gulf of Nicoya, but nothing ever came of the project.

=311. English Invasion of Nicaragua.=—The country was invaded in 1780 by an English expedition sent out from Jamaica under Captain Horatio Nelson, who subsequently became the great admiral. He proceeded up the San Juan River, and after some fighting captured by assault Fort San Juan at Castillo Viejo. Nelson and his force, however, were ill qualified to take care of themselves in that tropical country where drenching rains were constantly falling, and he was therefore obliged to abandon his plan

of taking possession of Lake Nicaragua and returned instead to Jamaica. The tropical fevers induced by exposure reduced the crew of his own ship, two hundred in number, to only ten after his return to Jamaica, and he himself nearly lost his life by sickness.

=312. Atlantic and Pacific Ship-canal Company.=—Subsequently to this period the Nicaragua route attracted more or less attention until Mr. E. G. Squier, the first consul for the United States in Nicaragua, negotiated a treaty between the two countries for facilitating the traffic from the Atlantic to the Pacific Ocean by means of a ship-canal or railroad in the interest of the Atlantic and Pacific Ship-canal Company, composed of Cornelius Vanderbilt, Joseph L. White, Nathaniel Wolfe, and others. It was at this time that the Nicaragua route became prominent as a line of travel between New York and San Francisco. Ships carried passengers and freight from New York to Greytown, then trans-shipped them to river steamboats running up the San Juan River and across the southerly end of the lake to a small town called La Virgin, whence a good road for 14 miles overland led to the Pacific port of San Juan del Sur. Pacific coast steamships completed the trip between the latter port and San Francisco.

=313. Survey and Project of Col. O. W. Childs.=—This traffic stimulated the old idea of a ship-canal across the Central American isthmus on the Nicaragua route to such an extent that Col. O. W. Childs, an eminent civil engineer, was instructed by the American Atlantic and Pacific Ship-canal Company to make surveys and examinations for the project of a ship-canal on that route. The results of his surveys, made in 1850-52, have become classic in interoceanic canal literature. He concluded that the most feasible route lay up the San Juan River from Greytown to Lake Nicaragua, across that lake, and down the general course of the Rio Grande on the west side of Nicaragua to Brito on the Pacific coast. This is practically identical with the route adopted by the Isthmian Canal Commission now (1902) being discussed in Congress.

=314. The Project of the Maritime Canal Company.=—The project planned by Col. Childs, like those which preceded it, had no substantial issue, but the general subject of an isthmian canal across Nicaragua was, from that time, under almost constant agitation and consideration more or less active until the Maritime Canal Company of Nicaragua was organized in February, 1889, under concessions secured from the governments of Nicaragua and Costa Rica by Mr. A. G. Menocal. This company made a careful examination of all preceding proposed routes, and finally settled upon a plan radically different in some respects from any before considered. The Caribbean end of the canal was located on the Greytown Lagoon west of Greytown. From that point the line followed up the valley of the Deseado River and cut across the hills into the valley of the San Juan above its junction with the San Carlos. A dam was to be constructed across the San Juan River at Ochoa, below the mouth of the San Carlos, so as to bring the surface of Lake Nicaragua down to that point. From its junction with the San Juan River the canal line followed that river to the lake, across the latter to Las Lajas, and thence down the Rio Grande to the Pacific coast at Brito. It was contemplated under this plan to carry the lake level to a point called La Flor, 13.5 miles west of the lake, and drop down to the Pacific from that point by locks suitably located. After partially excavating the canal prism for about three quarters of a mile from the Greytown Lagoon, constructing a line of railroad up the Deseado valley, as well as a telegraph line, and doing certain other work preparatory to the actual work of construction, the Maritime Canal Company became involved in financial difficulties and suspended operations without again resuming them.

[Illustration: Breakwater of the Maritime Canal Company. The closed former entrance to Greytown harbor is shown on the left.]

=315. The Work of the Ludlow and Nicaragua Canal Commissions.=—In 1895 and again in 1897 two commissions were appointed by the President of the United States to consider the plans and estimates of the Maritime Canal Company in the one case, and the problem of a ship-canal on the Nicaragua route in the latter. Neither of these commissions, however, had the funds at its disposal requisite for a full and complete consideration of the problem. In 1899, therefore, the Isthmian Canal Commission was created by Act of Congress, and appointed by the President of the United States, to determine the most feasible and practical route across the Central American isthmus for a canal, together with the cost of constructing it and placing it under the control, management, and ownership of the United States. This commission consisted of nine members, and included civil and military engineers, an officer of the navy, an ex-senator of the United States, and a statistician. It was the province and duty of this commission to make examinations of the entire isthmus from the Atrato River in the northwestern corner of South America to the western limits of Nicaragua for the purpose of determining the most feasible and practical route for a ship-canal between those territorial limits. This brings the general consideration of the isthmian canal question to the Nicaragua route in particular, to which alone attention will be directed in this part.

=316. The Route of the Isthmian Canal Commission.=—The Isthmian Canal Commission adopted a route practically following the San Juan River from near Greytown to the lake, across the latter to Las Lajas on its westerly shore, and thence up the course of the Las Lajas River, across the continental divide into the Rio Grande valley, and down the latter to Brito at the mouth of the Rio

Grande on the Pacific coast. As has already been stated, this is practically the line adopted by Col. Childs almost exactly fifty years ago. It is also essentially the route adopted by the Nicaragua Canal Commission appointed in 1897, and which completed its operations immediately prior to the creation of the Isthmian Canal Commission. The amount of work performed in the field under the direction of the commission can be realized from the statement that twenty working parties were organized in Nicaragua with one hundred and fifty-nine civil engineers and other assistants, and four hundred and fifty-five laborers.

=317. Standard Dimensions of Canal Prism.=—By the Act of Congress creating it, the latter commission was instructed to consider plans and estimates for a canal of sufficient capacity to accommodate the largest ships afloat. In order to meet the requirements of those statutory instructions the commission decided to adopt 35 feet as the minimum depth of water in the canal throughout its entire length from the deep water of one ocean to that of the other, wherever the most feasible and practical route might be located, the investigations of the commission having shown that the final location to be selected must narrow down to a choice between the Panama and the Nicaragua routes. It was further decided by the commission that the standard width of excavation at the bottom of the canal should be 150 feet, with 500 feet for the ocean entrances to harbors, and 800 feet in those harbors. Greater widths than that of the bottom of standard excavations were also adopted for river and lake portions. The slopes of the sides of the excavation were determined to be 1 vertical on 1½ horizontal for firm earth, but as flat as 1 vertical on 3 or even 6 horizontal for soft mud or silt in marshy locations. In rock cutting below water the sides of the excavation would be vertical, but as steep as 4 vertical on 1 horizontal above water.

[Illustration]

[Illustration: Standard Sections adopted by the Isthmian Canal Commission.]

The longest ship afloat at the present time (1902) is the Oceanic of the White Star Line, and its length is about 704 feet. The widest ships, i.e., the ships having the greatest beam, are naval vessels, and at the present time none has a greater beam than about 77 feet. In order to afford accommodation for further development in both length and beam of ships without leading to extravagant dimensions, the commission decided to provide locks having a usable length of 740 feet with a clear width of 84 feet. These general dimensions meet fully the requirements of the law, and were adopted for plans and estimates on both the Panama and Nicaragua routes.

=318. The San Juan Delta.=—The entire Central American isthmus is volcanic in character, and this is particularly true of the country along the Nicaragua route with the exception of the lowlands immediately back of the ocean shore line in the vicinity of Greytown. From the latter point to Fort San Carlos, where the San Juan River leaves the lake, is approximately 100 miles. With the exception of the 15 miles nearest to the seacoast the San Juan River runs mostly through a rugged country with high hills densely wooded on either side. The soil is mostly heavy clay, although the bottom of the valley immediately adjacent to the river is largely of sandy silt with some mixture of clay. Between the hills back of Greytown and the seacoast the country is almost a continuous morass covered with coarse grasses and other dense tropical vegetation, but with a number of small isolated hills projecting up like islands in the surrounding marsh, and interspersed with numerous lagoons. All this flat country has the appearance of forming a delta through which a number of mouths of the San Juan River find their way. One of these, called the Lower San Juan, empties into the Greytown Lagoon, but the main mouth of the San Juan, called the Colorado, branches from the main river at the point where the Lower San Juan begins, about 13 or 14 miles from the ocean. The Colorado itself is composed of two branches, and at the place where it empties into the sea there are a number of long narrow lagoons parallel to the seashore, appearing to indicate comparatively recent shore formation. Again, a small river called the Rio San Juanillo leaves the main river 3 or 4 miles above the junction of the lower San Juan and the Colorado, and pursues a meandering course through the low marshy grounds back of Greytown, and finally again joins the Lower San Juan near the town. This marshy lowland is underlaid by and formed largely of dark-colored sand brought down mostly from the volcanic mountains of Costa Rica by two rivers, the San Carlos and the Serapiqui, the former joining the San Juan about 44 miles and the latter about 23 miles from the sea.

[Illustration: Greytown Lagoon (formerly Greytown Harbor), showing Greytown in the Distance.]

=319. The San Carlos and Serapiqui Rivers.=—Both those Costa Rican rivers are subject to sudden and violent floods, and they bring down large quantities of this volcanic sand, the specific gravity of which is rather low. The San Carlos bears the greater burden of this kind. In fact its bed, even when not in a state of flood, is at many points at least composed of moving sands. Both rivers are clear-water streams except in high water stages. Below the junction of the San Carlos the San Juan is necessarily in times of floods a large bearer of silt and sand, but above that point it carries little or no sediment. There are no streams of

magnitude which join the San Juan between the lake and the San Carlos.

=320. The Rapids and Castillo Viejo.=—About 54 miles from the ocean are the Machuca Rapids, and from that point to a distance of about 75 miles from the ocean other rapids are found, the principal of which are the Castillo and the Toro. The Castillo Rapids are at the point called Castillo Viejo, where there is located an old Spanish fort on the top of the high hill around the base of which the river flows. The town of Castillo Viejo has a small population of perhaps 500 to 600 people. It is a place with historical associations, to which reference has already been made. It was here that Captain (afterwards Admiral) Nelson captured the Spanish fort in 1780. It is a place of some importance in connection with the river traffic in consequence of necessary transhipment of freight and passengers to overcome the rapids.

=321. The Upper San Juan.=—The upper reaches of the San Juan within about 20 miles of the lake are bordered with considerable marshy ground. In the vicinity of its exit from the lake there is a wide strip of soft marshy country around the entire southeastern shore.

=322. The Rainfall from Greytown to the Lake.=—The entire country between Greytown and the lake is intensely tropical, and the vegetation is characteristically dense. It is particularly so at Greytown, where the total annual rainfall sometimes reaches as much as 300 inches. It rains many times in a day, and nearly every day in the year. The strong easterly and northeasterly trade winds, heavy-laden with the evaporation from the tropical sea, meet the high ground in the vicinity of Greytown and precipitate their watery contents in frequent and heavy showers. The general course of the San Juan valley is a little north of west or south of east, and the trade winds appear to follow the course of the valley to the lake. The rainfall steadily decreases as the seashore is left behind, so that at Fort San Carlos, the point of exit of the river from the lake, the annual precipitation may vary from 75 to 100 inches. There is no so-called dry season between the lake and the Caribbean Sea, although at Fort San Carlos the rainfall is so small between the middle of December and the middle of May that that period may perhaps be considered, relatively speaking, a dry season. It is evident, therefore, that all the conditions are favorable to luxuriant tropical growths over this entire eastern portion of the canal route, and the coarse grasses, palms, and other tropical vegetation found in it are indescribably dense. The same general observation is applicable to the forest and undergrowth throughout the entire course of the river from Greytown to Fort San Carlos. All of the high ground is heavily timbered, with undergrowth so dense that no survey line can be run until it is first completely cut out. That observation holds with added force throughout the swampy country adjacent to the seashore. All the heavy forest growth carries dense vines and innumerable orchids, which so cover the trunks and branches of trees as in many places completely to obscure them.

[Illustration: The Maritime Canal Company’s Canal Cut leading out of Greytown Lagoon.]

=323. Lake-surface Elevation and Slope of the River.=—The lake surface has an area of about 3000 square miles and varies in elevation with the amount of rainfall in its basin from about 97 or 98 to perhaps 110 feet above the ocean. The average elevation can probably be taken at about 104 feet above the sea. The length of the lake is about 103 miles, with a greatest width of 45 miles. The area of its watershed is about 12,000 square miles. Inasmuch as the length of the San Juan River from the ocean to the lake is but a little more than 100 miles, its average fall is seen to be about 1 foot per mile. The greatest slope of the river surface is at Castillo Rapids, where it falls about 6 feet in ■ of a mile. At the Machuca Rapids it falls about 4 feet in 1 mile. Fro

Introduction

No truly great book needs an explanation of its aim and purpose. A great book just grows, as has this Book of Wonders.

It began with the attempt of a father to answer the natural questions of the active mind of a growing boy. It developed into a nightly search for plain, understandable answers to such questions as “What makes it night?” “Where does the wind begin?” “Why is the sky blue?” “Why does it hurt when I cut my finger?” “Why doesn’t it hurt when I cut my hair?” “Why does wood float?” “Why does iron sink?” “Why doesn’t an iron ship sink?” on through the maze of thousands of puzzling questions which occur to the child’s mind. It has grown until the answers to the mere questions cover practically the entire range of every-day knowledge, and has been arranged in such a form that any child may now find the answer to his own inquiries.

As the mind of the child matures, the questions naturally drift toward the things which the genius of man has provided for his comfort and pleasure. We have become so accustomed to the use and benefits of these wonders produced by man that we generally leave out of our books the stories of our great industries, and yet the mind of the child wonders and inquires about them. We have so long worn clothes made of wool or cotton, that we have forgotten the wonder there is in making a bolt of cloth. Every industry has a fascinating story equal to that of the silkworm, which moves its head sixty-five times a minute while spinning his thousand yards of silk.

Can you tell What happens when we telephone? How a telegram gets there? What makes an automobile go? How man learned to tell time? How a moving-picture is made? How a camera takes a picture? How rope is made? How the light gets into the electric bulb? How glass is made? How the music gets into the piano? and hundreds of others that embrace the captivating tales of how man has made use of the wonders of nature and turned them to his advantage and comfort? The Book of Wonders does this with illuminating pictures which stimulate the mind and give a bird's-eye view of each subject step by step.

Where shall such a book begin? Shall it begin with the Story of How Man Learned to Light a Fire--he could not cook his food, see at night, or keep warm without a fire; or should it begin with How Man Learned to Shoot--he could not protect himself against the beasts of the forest, and, therefore, could not move about, till the soil or obtain food to cook until he knew how to shoot or destroy.

What was the vital thing for man to know before he could really become civilized? Some means, of course, by which the things he learned--the knowledge he had acquired--could be handed down to those who came after him so that they might go on with the intelligence handed down to them. This required some means of recording his knowledge. Man had to learn to write. Without writing there could be no Book of Wonders, and the book, then, begins naturally with the Story of Mow Man Learned to Write.

THE EDITOR.

How Man Learned to Write

It is a long time between the day of the cave-dwellers, with their instruments of chipped stone, and the present day of the pen. Yet wide apart as are these points of time, the trend of development can with but few obstacles be traced.

The story of the pen is a natural sequence of ideas between the first piece of rock scratched upon rock by prehistoric man, and the bit of metal which now so smoothly records our thoughts.

There was a time in the unwritten history of man when necessity prompted the invention of weapons, and the minds of these primitive men were concentrated upon this point. But the arts of war did not take up their entire time; some time must have been given to other pursuits. As the mind developed, and as an aid to memory, we find them carving, engraving, incising upon the rocks their hieroglyphics, which took the form of figures of men, habitations, weapons, and the animals of their period.

[Illustration: THE STYLUS]

How Did Writing First Come About?

An apparently difficult question to answer, since without writing there can be no record of its origin, and without records no facts; yet the deduction is so clear that the answer is simple. Somewhere far, far back in the dawn of the world, back in the beginning of human history, in the epoch which we have now named the Quaternary Period, man lived in a dense wilderness surrounded by the wildest and most ferocious beasts. His home was a cave, exposed to the dangers incidental to that time and his surroundings, and he was of necessity compelled to look about for means of defense. With this idea in mind, he found that by striking one stone against another he knocked off chips, which chips could be used as arrow-heads, spears and axes. Following along these lines he discovered that by rubbing one of these chips against another there was left a mark, which was the first imitation of writing; that the sharper the edge of the chip, the deeper was the scratch, and consequently the more distinct the mark.

[Illustration: EARLIEST WAYS OF WRITING

THE FIRST IMITATION OF WRITING]

Next it was discovered that certain stones, such as flint, serpentine and chalcedony, marked more readily than others; that the elongated chip was handled with more facility; that by rubbing one stone against another the finest possible points and edges might be obtained. Thus in the Age of Stone was the long, tapering instrument of stone, the first pen, the Stylus, originated.

Then came the time, known as the Bronze Age, when men learned to hammer metal into shapes, and metal having many advantages over stone, the stylus of stone gave way to one of iron. So we find that in the time of the Egyptians, about fourteen or fifteen centuries B.C., an iron stylus was in use for marking on soapstone, limestone and waxed surfaces. An improvement in this metal stylus was that the blunt end was convex and smooth, the purpose of which was to erase and smooth over irregularities. In

some cases it was pointed with diamonds, which gave it greater cutting properties. The iron stylus was also used by the Egyptians of that period, as well as in later times, with a mallet, after the manner of the modern chisel (which indeed it resembled) for cutting out inscriptions on their monuments.

[Illustration: THE BRUSH]

~WRITING FLUIDS HELPED DEVELOPMENT~

In course of time a marking fluid was discovered, and this made necessary a writing instrument which could spread characters on parchment, tree-bark, etc. Thus it was found that by putting together a small bunch of hairs, arranging them in the shape of an acute cone, and fastening them together in some manner, an instrument could be made which would carry fluid in its path, and thus make a mark of the desired shape. The hair best adapted for the purpose was found to be camel's hair, while that of the badger and sable was also used. A tube cut from a stalk of grass answered for a holder. The hairs were held together by a piece of thread which was then drawn through the tube, thus making the first writing instrument to be used in conjunction with ink, the Brush.

[Illustration: HOW THE CHINESE IMPROVED METHODS]

Just when the Brush came into existence is not definitely known, but with this instrument the great Chinese philosopher Confucius wrote his marvelous philosophy. The Brush as a writing instrument is generally associated with the Chinese, because the Chinese use this instrument even to the present day, it being especially adapted to their letters and mode of writing. We have now a pen (brush), as well as an ink, but the material upon which the people of that age wrote, in lieu of paper, was still very crude, parchment and tree-bark being most commonly used.

[Illustration: THE QUILL]

~THE EARLIEST FORMS OF PAPER~

Just as the discovery of an ink wrought a change from the Stylus to the Brush, so the advent of papyrus, a paper made from the papyrus plant, which was much finer and more economical than parchment, brought with it a pen better adapted for this material. It was found that the Reed, or Calamo, as it was called, which grew on the marshes on the shores of Egypt, Armenia and the Persian Gulf, if cut into short lengths and trimmed down to a point, made an admirable pen for this newly discovered paper. This was the true ancient representative and precursor of the modern pen. The use of the Reed can be traced to a remote antiquity among the civilized nations of the East, where Reeds are in use now as instruments for writing.

[Illustration: HOW THE MONKS DID THEIR WRITING]

The introduction of a finer paper rendered necessary a finer instrument of writing, and the quill of the goose, swan, and, for very fine writing, of the crow, was found to be well adapted. Immense flocks of geese were raised, chiefly for their quills. The earliest specific allusion to the quill occurs in the writings of St. Isadore de Seville, seventh century, although it is believed to have been in use at an earlier period. The quill was used for many centuries. Most of the writing during its reign was done in the monasteries by the monks, and in the eighteenth century, when quill-making became quite an art, every monk and every teacher was expected to be proficient in the art of making a pen from a quill. The preliminary process of preparing the quills was first to sort them according to their quality, dry in the hot sand, then clean them of the outer skin, and harden by dipping in a boiling solution of alum and diluted nitric acid. During the last century many efforts were made to improve the quill, its great defect being speedy injury from use. Ruby points were fitted to the nib, but this was found impracticable on account of the delicacy of the work. Joseph Bramah devised, in 1809, a machine for cutting the quill into separate nibs for use in holders, thus making several pens from one quill and anticipating the form of the modern pen.

[Illustration: THE STEEL TUBE PEN]

[Illustration: THE FIRST STEEL PEN]

The quill held sway as writing instrument for many years, and with it the greatest masterpieces in literature have been written. Many attempts, however, had been made to supersede the quill by a pen not so easily injured by use, but it was not until about 1780 that, after much experimenting and numerous failures, Mr. Samuel Harrison introduced the first metallic pen.

~THE INVENTION OF THE PEN~

This pen was made as follows:

A sheet of steel was rolled in the form of a tube. One end was cut and trimmed to a point after the manner of the quill, the seam where both edges of the tube met forming the slit of the pen. This was soon after improved upon by cutting a rough blank out of a thin sheet of steel, which blank was filed into form about the nib, rounded, and with a sharp chisel marked inside where the slit was to be in the finished pen. After tempering, the nib was ground and shaped to a point suitable for fine or broad writing, as required.

[Illustration: THE MODERN STEEL PEN]

[Illustration: THE MODERN WRITING PEN]

Once started, the steel pen made rapid strides in improvement. Mr. James Perry, in 1824, started in England the manufacture of pens on a large scale, and to him as well as Gillott is due the many improvements which followed.

Perry was the first to manufacture “slip” steel pens, up to this time the pen and holder being one piece.

“In times of yore, when each man cut his quill With little Perryian skill; What horrid, awkward, bungling tools of trade Appeared the writing instruments, home made!”

~THE MODERN WAY OF WRITING~

The steel pen of the present day has reached the pinnacle of perfection, and the method of manufacture of this little but mighty instrument of writing, though of extreme interest, is practically unknown by the general public. To explain in detail the development from the rough steel to the finished pen would needs make a book in itself. And as it has been our intention to dwell, not upon the manufacture of the pen, but to trace its history and development from its most crude form, the Stylus, to the perfect and smooth-writing steel pen of to-day, we will close our story with the well-worn epigram of old, grim Cardinal Richelieu:

“Beneath the rule of men entirely great, The Pen is mightier than the Sword!”

How a Steel Pen is Made

In the picture on the following page, we see the various processes required in making a steel pen, together with a description of each process:

Raw Material.--The sheet steel is cut into strips of a convenient length and width, and then rolled cold to the exact gauge necessary, according to the pen to be manufactured.

Cutting the Blank.--This is a mechanical operation, and is effected with the aid of a screw press, in which a pair of tools corresponding with the shape of the pen has been fixed. On pulling a lever the screw descends, driving the punch into the bed, which cuts a blank with a scissors-like action, from the strip of steel.

Marking the Name.--This is done by means of a punch fixed in the hammer of a stamp, worked by the foot. The blanks are rapidly introduced between guides fixed on the bed of the stamp, and as soon as the hammer has fallen the blank is thrown out and a new one introduced.

Piercing.--The tools for this operation are of a delicate character. The blanks are fed by hand, as above explained, and the hole punched by a screw press. This is a most important process; the pierce hole and slide slits determine the elasticity and regulate the flow of the ink on the pen.

Annealing or Softening.--The blanks are still moderately hard and before raising, it is necessary to soften them by heating to a dull red, and allowing them to gradually cool.

Raising.--The operator places one of the soft blanks on a die to which guides are affixed to keep it in position; then by moving the handle of the press, the screw descends, forcing a die which rounds the blank into the form of a pen.

Hardening.--The pen is now too soft, and is hardened by heating and the immersing in oil while hot, after which it is thoroughly cleansed from all grease.

Tempering.--The pens are now hard but very brittle, and in order to correct this defect they are placed in an iron cylinder, and kept revolving over a gas or charcoal fire until they acquire a proper temper.

Scouring.--After soaking in diluted sulphuric acid, the pens are placed in iron cylinders containing fine stone and water, or fine sand, and revolved for several hours. When taken from these cylinders they are bright and smooth.

Grinding.--This is a process performed by hand on a “bob,” or wooden wheel covered with leather and dressed with emory, revolving at high speed. A light touch on the emory wheel grinds off the surface between the pierce hole and the point, to obtain proper action and to assist the flow of ink.

Slitting.--This is a hand process performed with a press, the cutters being as sharp as razors. The pen is placed in position by means of guides, and must be cut with utmost precision from the pierce hole to the point, the point must be divided exactly in the middle, the least variation making the pen defective.

Coloring and Varnishing.--The pens having been polished to a bright silver color are placed in an iron cylinder and kept revolving over a gas or charcoal fire until the tint required is produced. They are then immersed in a bath of shellac varnish, and afterwards dried in an oven.

Examination.--Every steel pen passing through the factory is most carefully examined before being boxed, and should the least fault be found, it is at once rejected.]

Why Does a Pencil Write?

You can use a pencil to write with or to make marks, because the pencil wears off if you are scratching it on a surface that is rough enough to make it do so. Writing, you know, is only a way of making marks in such a manner as to make them mean something. You cannot write with a pencil on a pane of glass, because the glass is so smooth that when you move the pencil over its surface, the pencil will not wear off. To prove to yourself that the tip of the pencil constantly wears off when you write, you have only to recall that when you write with it a pencil keeps getting shorter and shorter. A slate-pencil will wear down short by merely writing with it, but a lead-pencil must be sharpened--that is, you must keep cutting away the wood in order to get at the lead inside.

Why Can’t I Write on Paper With a Slate-pencil?

You cannot do so, because it takes something with a rougher surface than paper to wear off the point of a slate-pencil. A slate is used to write on with slate-pencils, because slate wears off the end of the pencil easily, and also because you can rub out the

writing on a slate with water. Lead-pencils are used for writing on paper, but you must have a rough surface on the paper to write on even with a lead-pencil. Some kinds of papers have such a smooth surface that you cannot write on them with a lead-pencil.

How Does a Pen Write?

Writing with a pen, however, is quite different from writing with any kind of pencil, because in writing with ink we do not wear off the end of the pen, but have the ink flow from the pen. For this purpose we must have a surface that will absorb the ink from the pen, and draw the ink down off the pen and make it flow. A slate has no power of absorption and therefore cannot draw the ink. A piece of blotting paper is the best kind of paper for absorbing ink, but it is too much so for writing purposes. For writing with ink we need a comparatively hard surfaced paper that has absorbent qualities, but not too absorbent.

How Does a Blotter Take Up the Ink of a Blot?

It is because the blotter has a very excellent ability to absorb some liquids. The thinner the liquid the more easily the blotter will absorb it. Ink is thin--being mostly water--the blotter is of a loose texture and has a rough surface. This gives the blotter the ability to pick up the ink, just as a sponge would do. A sponge has what is called the power of capillary attraction and so has the blotter.

Where Does Chalk Come From?

Deposits of chalk are found on some shores of the sea. A piece of chalk such as the teacher uses to illustrate something on the blackboard at school consists of the remains of thousands of tiny creatures that at one time lived in the sea. All of their bodies excepting the chalk--called carbonate of lime in scientific language--has disappeared and the chalk that was left was piled up where it fell at the bottom of the ocean, each particle pressing against the other with the water pressing over it all until it became almost solid. It took thousands of years to make these chalk deposits of the thickness in which they are found. Later on, through changes in the earth's surface, the mountain of chalk was raised until it stood out of the water and thus became accessible to man and school teachers.

How Did Men Learn to Talk?

Talking and the words used came into being through the desire of men to communicate with each other. Before words became known and used man talked to those about him by the use of signs, gestures and other movements of the body. Even to-day when men meet who cannot talk the same language they will be seen trying to come to an understanding by the use of signs and gestures and generally with fair results. The need of more signs and gestures to express a constantly increasing number of objects and thoughts led to the introduction of sounds or combination of sounds made with the vocal cords to accompany certain signs and gestures. In this way man eventually developed a very considerable faculty for expressing himself. Sign by sign, gesture by gesture and sound by sound language was slowly developed. A man would be trying to explain something to another by sign or gesture and to make it more clear would make a sound or combination of sounds to put more expression into his efforts. Finally the other man would understand what was meant and he would tell some one else, using the same signs, gestures and sounds. Later on it would develop that to express thus any certain thought, act or the name of a thing, all of the people in the community would make this same combination of sounds, signs and gestures to express the same thing. Finally the gestures and signs would be dropped and it was found that people understood perfectly what was meant when only the sound or combination of sounds was produced. That made a word. All the other words were made in the same way, one at a time, until we had enough words to express all the ordinary things and the combination of words became a language. The children learned the language by hearing their parents talk it, and that is how men learned to talk.

How Did Shaking the Head Come to Mean "No"?

The origin of this method of indicating "No" is found in the result of the mother's efforts in the animal kingdom of trying to feed her young. A mother animal would be trying to get her young to accept the food she brought them and tried to put it in their mouths. Perhaps, however, the young animal had had sufficient food or did not fancy the kind of food offered. The natural thing to do under the circumstances would be to close the mouth tight and shake the head from side to side to prevent the mother from forcing the food into the mouth. Thus we get the closed lips and the shaking the head from side to side to mean "No." In other words, that kind of a way of saying "No" came from an effort to say "I don't want any."

How Did a Nod Come to Mean “Yes”?

The idea of nodding to mean “Yes” comes from the opposite of the action which, as just described, indicates a “No.”

When the young animal was anxious to accept the offered food, it made an effort to get at the food quickly. Hence, the pushing forward of the head and the open mouth (always more or less opened when you nod to indicate “Yes”) and an expression of gladness. You will notice if you see anyone nod the head to indicate “Yes” that the lips are open rather than closed, and that there is always a smile or an indication of a smile to accompany it. In other words, the nod to mean “Yes” is only another way of saying “I shall be pleased.”

Why Do We Count in Tens?

When man even in his uncivilized state found it necessary to count, the only implements at hand were his fingers and toes, and as he had ten toes and ten fingers, he naturally began counting in tens, and has been doing so ever since.

When we to-day count on our fingers we confine ourselves to our fingers leaving our toes stay in our shoes, where they naturally belong. But the first men who counted used both fingers and toes, and so he was able to count twenty before he had to begin over again, while little children to-day, when they count with their fingers, must begin where they started after they reach ten.

What Does Man Mean by Counting Himself?

The expression “counting himself” was originated by the first man who counted. Such a man would count all of his fingers and toes and the result would be twenty. Then, so that he would remember the number of times he had counted himself, he made a mark some place each time he reached twenty. The mark he made was a mere scratch in the dirt or on a hoe or something else. To make a scratch you merely, of course, score the surface of whatever you happen to be scratching on, and that is how it happened that the word “score” in our language to-day means as a term in counting, twenty.

There has been a great effort made to change our system of counting in tens to one where you count in twelves. That would fit in very well with our system of measuring which is based on the foot of twelve inches, and of our calendar for recording the passage of time which has twelve months. There are many arguments in favor of this change, among the principal of which is the fact that it would make our problems of division much easier, for our ten can be evenly divided by but two of our single figures, two and five, whereas twelve can be evenly divided by four of our single figures, viz., two, three, four and six. It is believed that sooner or later the system of counting by twelve instead of ten will be adopted by the entire world for counting everything. As it is now we do part of our counting by one system and part of it by another.

Where Did All the Names of People Originate?

There is no scientific plan by which people get their names. There is not much except curious interest to be gleaned from the study of how people got their names.

In the earliest days of the world, or at least as soon as men had learned to speak by sounds, all known persons, places and groups of human beings must have had names by which they could be spoken of or to, and by which they were recognized. The study of these names and of their survival in civilization enables us in certain instances to tell what tribes inhabited certain parts of the earth now peopled by descendants of an entirely different race and of another speech altogether. We learn such things from the names of mountains and other things, for instance, which still cling to them.

The story of personal names is very complex, but comes from very simple beginnings. The oldest personal names were those which indicated a group of people rather than individuals who may have been actually related to each other or even bound together for reasons of protection or other convenience. In the races of Asia, Africa, Australia and America examination shows that groups of people who considered themselves to be of the same relationship, attached to themselves the name of some animal or other object, whether animate or inanimate, from which they claimed to be descended. This animal or object was called the “totem,” and thus the earliest and most widely spread class and family names are totemistic. Such groups called themselves by names from wolves, turtles, bears, suns, moons, birds, and other objects, and these people wore badges with pictures of the animal or object from which they took their names to identify them to other people.

When, then, we come to investigate the giving of personal names among the tribes, we see that most uncivilized races gave a name to each new-born infant derived from some object or incident. So a new-born member of the “Sun” tribe would be named “Dawn,” and would be known as “Dawn” of the “Sun” tribe; or perhaps a new-born son of the tribe of “Wolf” would be called “Hungry,” and be known as “Hungry Wolf.” A member of the “Cloud” tribe would be named “Morning,” because he was born in the morning. He would always be known as “Morning Cloud.”

Later, as society became more established and paternity became recognized, we find the totem name give way to a gentile name. Among the Greeks and Romans the system was early adopted and proved satisfactory. Thus we have Caius Julius Caesar. Caius indicates that he is Roman; Julius is the gentile name given him and the Caesar a sort of hereditary nickname. On the other hand, the early Greeks began the system of introducing a local name instead of the gentile name. Thus Thucydides (obtained from the grandfather), the son of Olorus, of the Deme (township) of Halimusia.

~HOW DIFFERENT NAMES ORIGINATED~

This was all right and suited the purposes of the Greeks and Romans, who had plenty of time to give full explanations in this way. But in Europe, for instance, civilization demanded more speed, and the increase of population demanded more names, so that nicknames and names indicating personal descriptions and peculiarities came into use. Such names as Long, Short, Small, Brown, White, Green and others of the same kind came from this source, and as families grew these surnames stuck to the family and parents gave their children Christian names to further distinguish them as individuals. Other surnames such as Fowler, Sadler, Smith, Farmer, etc., became attached to people because of the occupations in which they were engaged, and yet other names were derived from places. The owner of an extensive estate would be designated by a Christian name which might be George (after his King) and then to indicate his landownership, von (meaning of) Wood, making the combination of George von Wood, meaning George, the owner of the place called Wood. On the other hand, he might have working for him a laborer who lived at the place and, if his name was Hiram, they would, to indicate where he belonged, put the Wood after the Hiram; but, lest there be confusion as to his class, they would put an At before the Wood and make him Hiram Atwood, indicating his Christian name, where he worked and the fact that he was not a landowner.

Many other names were invented in similar manner. When Adams became so common that there would likely be confusion on account of there being so many of them, a son of one of the Adams family would add to the name the fact that he was a son by writing his name Adamson, and thus start a new family name. Thus, in the same way also came Willson, Clarkson, and other names of that kind.

For a long time the Jews had only one word for a name, such as Isaac, Jacob, Moses, etc. They became so numerous that it was impossible to distinguish them, and so a commission was named to give surnames to all the Jews in addition to their other names. As the race was then, as now, held in derision by the rulers of many nations into which the tribe had become scattered, the people who had charge of the naming of the Jews took advantage of the opportunity to make sport of them, and gave them such names as

Rosenstock (Rose bush),

Rosenszweig (Rose twig),

Rosenbaum (Rose tree),

Blumenstock (Flower bush),

Blumenthal (Flower valley),

etc., etc.

Our Christian names are from similar sources, and while many of them are well selected because of their beautiful meanings, there are many of them which mean nothing as words as they were only invented for the purpose of giving a new name to a new child.

Why Can You Blow Out a Candle?

When you light a candle it burns, because the lighted wick heats the wax sufficiently to turn it into gases, which mix with the oxygen in the air and produce fire in the form of light. You know it is not easy to light a candle quickly. You must hold the lighted match to the wick until the wax begins to melt and change to gases. As long as the wax continues hot enough to melt and turn to gas the

candle will burn until all burned up; but if there is a break in the continuous process of changing the wax to gas, the light will go out. Now, when you blow at the lighted candle, you blow the gases which feed the flame away from the lighted wick, and this makes a break in the continuous flow of gas from the wax to taper, and the light goes out.

[Illustration]

The Story in a Photograph

How Does a Camera Take a Picture?

When we look upon the surface of a mirror we see the image of ourself and our surroundings. The extent of the view depends upon the size of the mirror and the distance we are standing from it.

If we hold the mirror close to our face we see only the face, or perhaps but a portion of it, and the farther away we are the more the mirror will reflect, only, of course, the various images will be smaller. The mirror reflecting exactly what the eye sees, without doubt had a great influence in inducing the experiments that resulted in the process we call photography.

The taking of a photograph with a camera may in a way be compared with the action of your eyes, when you gaze upon your reflection in a mirror, or look at any object or view. Any object in a light strong enough to render it visible will reflect rays of light from every point.

Now, the eye contains a lens very similar in form to that used in a camera. This lens collects the rays of light reflected from the object looked at and brings them to a focus in the back of the eye, forming an image or picture of whatever we see, just as the mirror collects the rays of light and reflects them back through the lens of the eye.

Certain nerves transmit the impression of the image so focused in the back of the eye to the brain and we experience the sensation of sight.

What Is the Eye of the Camera?

The lens is the eye of the camera, and the process we call photography is the method employed to make permanent the image the eye or lens of the camera presents to a sensitive surface within the camera.

Fig. 1 shows a simple form of camera, it being merely a light tight box with a lens fitted to the front, and a means for holding a sensitive plate at the back, the plate being placed at just the right distance to focus the rays of light admitted through the lens in exactly the same manner as the rays of light pass through the lens of the eye and come to a focus in the back part of the eye.

Now, if we could look inside the camera we would note that the image was inverted, or upside down.

Fig. 2 will explain this.

The rays of light from “A” pass in a straight line through the lens “B” until they are interrupted by “C,” upon which they strike, forming an upside down image of the object “A.” But, you exclaim, “we do not see things upside down.” No, we do not, because some mental process readjusts this during the passing of the impression from the eye to our brain.

Let us suppose we have our camera loaded with its sensitive plate or film. We select some object or view we wish to photograph, uncover the lens for an instant, and let the light impress the image upon the sensitive surface of the plate or film. Now, how are we going to make this image permanent?

If we were to examine the creamy yellow strip of film upon which the picture was taken there would seemingly be no difference between its present appearance and before the snapshot was made.

Now let us suppose that this strip of film is a little trundle bed, and in it tucked securely away from the light are many hundreds of little chaps called silver bromides, little roly-poly fellows lying just as close together as possible, and protected by a coverlet of pure white gelatine.

~HOW A PHOTOGRAPH IS DEVELOPED~

Until the sudden flash of light in their faces when the picture was taken, they have been content to lie still and sleep soundly. Now they are seized with a strange unrest, and each little atom is eager to do his part in showing your picture to the world. Alone they are powerless, but they have, all unbeknown to them, some powerful chemical friends, who, organized and aided by the photographer, will bring about their transformation. These chemicals, with the help of the photographer, form themselves into a society called the developer.

The photographer takes just so many of the tiny feathery crystals of pyro, just so many of the clear little atoms of sulphite of soda, and just so many little crystals of carbonate of soda, and tumbles them all into a beaker of clear cold water. Unaided by each other, any one of these chemicals would be powerless to help their little bromide of silver friends. The first of these chemicals to go to work is the carbonate of soda.

He tiptoes softly over to the trundle bed and gently begins turning back the gelatine covers over the little bromide of silver chaps, so that Pyro can find them in the dark.

It is Pyro's mission to transform the little silver bromides into silver metal, but he is rather an impulsive chap, so he is accompanied by sulphite of soda, who warns him not to be too rough, and whose sole mission is to strain his eagerness to help his friends.

"Go slow now," says Sulphite, "don't frighten the little silver bromides, or else you'll make them cuddle up in heaps, and the picture won't be as nice as if you wake them up gently and each little bromide stayed just where he belonged."

After all the little silver bromides that the light shone on have been transformed into metallic silver by the developer, another chemical friend has to step in and carry away all the little bromides that were not awakened by the flash of light.

This friend's name is "Hypo," and in a few minutes he has carried away all the little bromides that are still sleeping, so that the trundle bed with the now awakened and transformed silver bromides will, after washing and drying, be called a negative, and ready to print your pictures from.

If we take this negative, as it is called, and hold it up to the light, we will see that everything is reversed, not only from right to left, but also that whatever is white or light in color is dark in the negative, and that what would correspond to the darker parts of our picture are the lightest in the negative, and it is from these facts that we give it the name negative.

Now, to get our picture as it should be, we must place this negative in contact with a sheet of coated paper that is also sensitive to light.

So we place the negative and the sheet of sensitive paper in what is called a printing frame, with the negative uppermost, so that the light may shine through the negative, and impress the image upon the sheet of sensitive paper. Now, it stands to reason that if the lightest parts of our picture are the darkest in the negative that less light can pass through such portions of the negative in a given time, so that with the proper exposure to light the image upon the sheet of sensitive paper will be a correct picture of whatever the lens saw.

[Illustration: The swiftest thing that the human race has ever put into motion is the steel projectile of a twelve-inch gun. No human eye can follow its flight. Released at a pressure of forty thousand pounds to the square inch--in a heat at which diamonds melt and carbon boils--it hurls through the air at the rate of twenty-five miles a minute, and reaches the mark _ahead of its own sound_! (Pictures and story by courtesy of McClure's Magazine.)]

TWENTY-FIVE MILES A MINUTE

AN EXCLUSIVE STORY, ILLUSTRATED WITH A SERIES OF REMARKABLE PHOTOGRAPHS TAKEN WITH THE FASTEST CAMERA IN THE WORLD

BY CLEVELAND MOFFETT

~HOW SHOOTING SHELLS ARE PHOTOGRAPHED~

One of the most progressive branches of our military service is the Department of Coast Defenses, which, under the far-seeing guidance of General E. M. Weaver, holds our shores and harbors in a state of alert preparedness against foreign aggression. At Hampton Roads sits the Coast Artillery Board, composed of officers and consulting engineers to whom are referred all problems relating to coast artillery, and who have the responsibility of testing all new instruments proposed for artillery use. The purpose of

this article is to describe one among several notable achievements of the Hampton Roads Coast Artillery School, this particular work having been done by Captain F. J. Behr of the Coast Artillery Corps, who, after years of effort, has recently developed a system that makes it possible to take pictures of the swiftest moving bodies, the great steel projectiles of our biggest guns--to seize them with the camera's eye as they hurl through the air at enormous velocities or at the very moment of their emergence from the gun muzzles, and to preserve these images, never seen before, for military study and comparison. Captain Behr was ably assisted in this work by Engineer J. A. Wilson.

[Illustration: THE FASTEST CAMERA IN THE WORLD

The big gun, equipped with the fastest camera shutter in the world, about to be fired and the shell photographed.

For years a young officer of the Coast Artillery has been trying to devise a camera so incredibly swift that it will record every stage of this lightning flight from the gun-barrel to the target. At last he has succeeded. His photographs--some of them taken one hundred thousandth of a second apart--have revealed remarkable and unsuspected facts to the military world. The story of his invention had never before been told.]

Reckoning in Millionths of a Second.

Some of the increments and decrements of time involved in the series of photographs herewith published (several of them for the first time) are as small as one ten-thousandth part of a second. And Captain Behr has devised a method of taking photographs of projectiles as they arrive at a steel target and penetrate the target, inch by inch, that involves increments or decrements of time as small as the one hundred-thousandth part of a second. To the uninitiated it seems incredible that such infinitesimal divisions of time can be used in practical calculations; but every trained physicist knows that in wireless work scientists of to-day speak casually of experiments that take account of _two-tenths or one-tenth of a millionth part of a second_!

[Illustration: THE PROJECTILE EMERGING FROM MORTAR

In this photograph--the first of a remarkable series showing five stages of a moving projectile--the half-ton projectile seems to be standing still, but really it is traveling at the rate of 900 miles an hour. The gunners here work in concrete pits 34 feet high. Underneath the mounts are the powder magazines. Each pit has four mortars usually served by an entire Coast Artillery Company. The projectiles are the same as those used in the twelve-inch guns, but less powder is required because mortar projectiles are hurled high in the air, not straight at a vessel, and deliver their destructive blows downward from a great height.]

[Illustration: THE SMOKE RINGS WHICH APPEAR

This second photograph shows the projectile almost entirely out of the mortar. Its sharp nose may be seen above the "gas-ring" forming at its upper end. These "gas-rings," or "smoke-rings," come without warning, and only occasionally, perhaps once in eight or ten shots. They rise swiftly to the height of fifty or a hundred feet, growing larger and larger, and giving forth a weird, shrieking sound like a second projectile. Some insist that these "smoke-rings" are as hard as steel, owing to the enormous compression of their composing gases, and the story is told of a bird caught in the path of one of them and torn to pieces.]

What happened to the projectile after it leaves the gun, or after the discharge of the gun, and before the projectile has had time to issue from the gun-barrel? What is the action at the muzzle of gases generated? What shape do these gases assume as they leave the gun? What causes the much-discussed "gas-rings" that sometimes form when a mortar is fired, and oftener do not form? What phenomena attend the arrival of the projectile at a solid steel target? Is the steel actually fused by the heat of impact? Is it vaporized? Or what? These are some of the questions that Captain Behr set himself to solve, or to help in solving, as he worked out his methods of rapid photography. His aims were strictly military, but his results make fascinating appeal to the general imagination. Fancy doing anything in the one hundred-thousandth part of a second!

[Illustration: THE PROJECTILE HIDDEN BY THE SMOKE CONE

In the third photograph the smoke-cone is almost perfect and gives the famous "powder-puff" effect. It still hides the projectile, although the latter is traveling at a velocity that would take it from New York to Chicago in one hour. At night the "gas-rings" present a startling and fascinating appearance, burning with a reddish orange glow, and whirling with a complicated double motion, strange opalescent balls, like rings of Saturn. A study of these photographs--the first record ever made of the "gas-rings"--has led some experts to the conclusion that the cause of the rings is defective ramming of the projectile.]

[Illustration: THE PROJECTILE EMERGING FROM SMOKE CONE

The fourth photograph shows the projectile emerging from the smoke-cone about thirty feet above the muzzle of the mortar. The men who fire these mortars from the mortar-pits never see the distant target or vessel they are firing at, but point their mortars according to directions transmitted to them (usually by telephone) from observers at distant stations. And so great a degree of precision has been attained that, on certain practice occasions at Hampton Roads, a record of nine hits out of ten shots has been scored on a moving target five miles out in the ocean. This picture shows the smoke-cone as first seen by the human eye.]

Captain Behr's general idea was to utilize some phenomena connected with the discharge to actuate, by electrical connections, a mechanism that would work a rapid shutter in a properly placed camera. The phenomenon of concussion was tried first--the smash of air against a little swinging door; but this was much too slow. The projectile was hundreds of yards away before the camera had registered its picture. And that chance was gone!

[Illustration: THE PROJECTILE HIGH IN THE AIR

In the fifth photograph the projectile is seen entirely clear of the smoke-cone and well started on its long flight. Climbing into the sky at this steep angle, it will reach a height of from three to six miles before it begins to descend. There are harbors on our coasts guarded by so many guns and mortars that if these were fired simultaneously they could hurl against a given small area a converging rain of projectiles aggregating more than fifty tons in their combined mass. A minute later they could hurl another fifty tons against the same small area; and so on as long as the ammunition lasted.]

In the next trial, several months later, Captain Behr arranged to have the electrical connections made or broken by the movement of the gun-carriage itself in recoiling; but the result was unsatisfactory. Nor was he more fortunate at the succeeding target practice, when, having placed the apparatus farther forward on the parapet, he had the camera demolished by the force of the concussion and several blades of the rapid shutter broken. He was satisfied, now, that his effort to actuate the camera mechanism from the gun-carriage would never give the requisite precision in results, and he saw that he must work with a device functioning more reliably.

In the months that followed before the next target practice, the Captain did some experimenting, and finally determined making the projectile itself displace a length of piano-wire fixed across the muzzle of the gun, and thus actuate the electrical system and operate the shutter. In this way he eliminated troublesome variables of recoil, elasticity of the carriage, etc., leaving to determine only the time element of the electrical system to function. This result was admirable, and, after taking several similar pictures, the captain found that he could now operate with great precision--that is, he could get the same phase of the discharge with almost identical shapes of gas-cone and smoke-cloud, and he could get these every time.

In the fall of 1912 Captain Behr succeeded in obtaining a series of extremely rapid photographs showing a twelve-inch mortar battery in action. In taking these pictures the camera was placed on an elevation about ten feet above the concrete floor and about sixty feet back of the mortars. The electrical device for working the shutter was actuated by the mortar itself in its recoil. These pictures were taken in about one five-thousandth of a second--which is the more remarkable as the last two were taken in the shade after 4.30 A.M. The first three were taken about noon, in the sunshine, as the shadows show.

So great was the precision of the electrical device as to render possible the photographic recording of these mortar projectiles, moving at great velocities, in almost any desired position after the discharge, say two feet away from the muzzle, or six feet away, or twenty feet away, or right at the muzzle, as shown in the first mortar picture, where the great projectile has been caught in its flight half way out of the mortar.

Pictures Never Seen By the Human Eye.

~A CAMERA THAT IS FASTER THAN THE EYE~

It is interesting to note that of these five mortar pictures, representing five phases of the firing, only the last two are ever seen by the human eye. The far swifter camera, acting in about one five-thousandth of a second, has caught all these phases as reproduced here; but, to the ordinary observer standing by, the first visible impression after firing is that of the smoke-cone as developed in Number Four. The strange "powder-puff" effect shown in Number Three is never seen; nor the earlier effects in Numbers One and Two. Nor is any sound heard by an observer or by the gun crew until the third or fourth phase has been reached. This is a matter of simple calculation.

Sound travels through the air very slowly as compared with light, and in Numbers One, Two, and Three, although the crashing explosion has taken place and the projectile is already started on its long journey, the men (even the lanyard man, who is nearest), have heard nothing, since the sound-waves have not yet had time to reach their ears. Nor has the mortar itself had time to recoil, as it does presently, down into the well in the floor of the pit.

The men aboard the towing vessels that drag the floating targets during gun and mortar practice would seem to be in a dangerous position, since the tow-line is not more than two hundred yards long for guns and five hundred yards long for mortars, and a very slight error in aim or adjustment might cause a deviation of several hundred yards when the range is eight or ten thousand yards. As a matter of fact, such errors do not occur, and a gun-pointer who would make a right or left deviation from the target of ten yards, or at the most fifteen yards at a distance of five miles, would be considered unfit for his job. In one or two rare instances a towing vessel has been struck when a projectile has fallen short and then ricochetted to the right, as it invariably does owing to its rotation in that direction. The rifling of the gun-barrel causes this rotation.

[Illustration: This shows one of Captain Behr's earliest efforts to photograph the projectile from a twelve-inch gun. The man on the platform has been adjusting the electrical connections that actuate the camera mechanism. The halo effect at the muzzle of the gun is due to compressed air caused by the forward rush of the projectile. The projectile has not yet emerged from the muzzle of the gun. On the right is the place where the "Merrimac" and the "Monitor" had their famous fight.]

Sometimes these great projectiles ricochet several times, and go bounding over the water as a pebble skips along the surface of a mill-pond, only there may be the distance of a mile or more between these giant leaps.

The Projectile Travels Faster Than the Sound It Makes.

A strange phenomenon is witnessed by the observer on a towing vessel as he looks, rather uneasily perhaps, toward the distant shore battery, that seems to be firing straight at him. First there is a flash and a puff of smoke; then nothing for a period of seconds, while the projectile is on its way; then suddenly a great splash as the mass of iron strikes the water. Up to this moment there has been no sound of the discharge, no sound of the projectile, since it travels faster than the sound-waves; but now, _after_ it has buried itself in the ocean, is heard its own unmistakable voice, a low, buzzing _um-m-m-m_ approaching from the shore. The projectile itself has arrived _before_ the sound that it makes in transit, and the sound arrives afterward. Last of all is heard the boom of the discharge.

[Illustration: A GUN THAT PHOTOGRAPHED ITS OWN SHOT

In this beautiful picture the hurling projectile was itself the photographer: that is, in passing out of the gun-barrel, it broke a length of piano-wire stretched across the muzzle and thus automatically closed an electrical circuit that actuated the camera mechanism. And so rapid was the shutter that the great shot hurled forth in the discharge photographed here has not yet had time to issue from the smoke-cone, where it is still hidden.]

Owing to the great velocity of gun projectiles, it is almost impossible for an observer near the target to see them as they approach; but a trained eye can discern the slower moving mortar projectiles as they drop out of the sky, shrieking as they come, curving downward from a height of four or five miles, half a ton falling from a height of four or five miles.

[Illustration: EXPLODING A SUBMARINE MINE

This photograph illustrates another important form of coast defense--the submarine mine. A target about 5 by 5 feet, with a red flag at its apex, is towed across the mine-field, the mines being exploded electrically from a shore station several miles away. The methods of laying and exploding these mines are carefully kept secrets. In this case a charge of five hundred pounds of the newest explosive was used. Fragments of the shattered target and mine-buoy are seen at the right of the picture. Tons of water are hurled into the air by these explosions, and hundreds of fish are killed or stunned.]

It is difficult to realize what an enormous force is released when one of these twelve-inch guns is discharged. The pressure inside of the gun behind the projectile is between thirty-five and forty thousand pounds to the square inch. No engine or machine made by man produces anything like this pressure. The boiler pressure in steam-engines, or in big turbines driven by superheated steam, does not exceed two hundred or three hundred pounds to the square inch. The huge hydraulic presses that would crumple up a steel girder do not exert a pressure of more than one thousand pounds to the square inch. The only reason a gun-barrel can resist this pressure (forty thousand pounds to the square inch) is that it is built up in a series of concentric steel hoops or tubes shrunk

one over the other until there is a resistance capacity of from seventy thousand to ninety thousand pounds to the square inch. Even at rest, the barrels of these great guns are under such enormous compression, from being thus squeezed within these outer steel coverings, that, if the retaining steel jackets were suddenly cut, the tubes would blow themselves into pieces from the violent reaction of release.

Not only does this smokeless powder, burning inside these guns, produce enormous pressure, but it generates inconceivably great heat. Water boils at 100° Centigrade; iron melts at 1400°; platinum and the most resistant metals at 2900°; while the hottest thing on earth is the temperature of the electric arc, in which carbon boils. This temperature is between 3000° and 4000° Centigrade, and is believed to be the same as that of these great powder chambers when the gun is fired. Thus a diamond, the hardest substance known, would melt in the barrel of a twelve-inch gun at the moment of discharge. The consequence is that at each discharge of a big gun a thin skin of metal inside the barrel is literally fused, and this leads to rapid erosion of the softened surfaces under the tearing pressure of gases generated. The rifling is worn away; the band over the projectile becomes loose-fitting; and soon the huge gun, that has cost such a great sum, is rendered unfit for service. The life of a twelve-inch gun is only 450 rounds, that is, the gun would be worn out if fired every three minutes for a single day. After that a new life may be given it by boring out the inner tube and putting in a new steel lining.

A Secret for Which Foreign Governments Would Pay Millions.

A few words may be added about the formidable smokeless powder used in these great guns. This powder, in spite of its terrible power, is of innocent appearance, and a small stick of it may be held safely in the hand while it burns with a vivid yellowish flame. There is no danger of its exploding or detonating like gun-cotton, and yet it is made from gun-cotton, treated by a colloiding process that is one of our jealously guarded military secrets. There are foreign governments that would give millions to know exactly how this powder is made and how it is preserved for years without deterioration. The recent destruction of two ships of the French navy was due, it is believed, to deterioration of their smokeless powder.

[Illustration]

Why Do Some Eyes In a Picture Seem to Follow Us?

If a person’s picture is taken with the eyes of the person looking directly into the lens or opening of the camera, then the eyes in the picture will always be directly on and appear to follow whoever is looking at it. This is also true of paintings. If a subject being painted is posed so as to look directly at the painter, and the artist paints the picture with the eyes so pointed, then the eyes of the picture will follow you. When you are looking at a picture of a person and the eyes do not follow you, you will know at once that he was not looking at the camera or artist when the picture was being taken or painted.

[Illustration]

Where Does a Light Go When It Goes Out?

~WHY YOU CAN BLOW OUT A CANDLE~

To understand the answer to this question fully you will first have to learn what light is, and particularly that it is not the flame from the gas jet or of the lamp or candle that is actually the light, but that light consists of rays or waves in the ether, which is constantly in all space and even in our bodies, coming from the something that is burning. This in the instance above mentioned would be the gas burning as it comes out of the gas jet, the oil in the lamp as it comes up through the wick or the flame of the candle. We are apt to call a lighted gas jet a lamp, or a candle, light, because it is steady. Really, however, there is no such thing as keeping light in a room in an actual sense, for rays of light travel from the substance which produces them faster than anything else we know of in the world. The first thing a light wave does when it is once created is to go some place, and it does this at the rate of 186,000 miles per second. If it cannot penetrate the walls of the room it is either reflected back in the direction from which it came or transformed by the objects which it strikes into some other kind of energy.

When you look at the rays coming from a gas jet, you do not see one ray for more than, say the millionth part of a second, but because these rays of light come so fast one after the other from the burning jet and spread in all directions, they seem to be continuous.

So you see that the rays of light are going away as fast as they are coming from the gas jet. They either go on as light or, as said above, are changed into other forms of energy when they strike things they cannot penetrate in the form of light, or rather one thing, which is heat. A large part of it goes into the air in the room in the form of heat, as you well know, now that it is called to your attention. Some of it goes into the furniture and some of it is changed into another form of heat, which, combining with the chemicals in other things it mixes with, changes their appearance and usefulness. As, for instance, the carpets and hangings in the room, the colors of which become faded when exposed to light rays too much. The heat from the light rays is responsible for the fading of colors in our garments as well.

When you “put out the light,” as we say, or turn off the gas, you cut off the source of light. Really, then, our expression that “the light goes out” is only true while the gas is lighted, for from the flaming gas jet the light is going out all the time, whereas when the gas is turned off no light is being produced, and when you turn off the gas you do not turn out the light, but only that which makes light.

Why Does a Fire Go Out?

Fire will go out naturally when there is nothing left to burn, or it will go out if it cannot secure enough oxygen out of the air to keep it going. In the first case it dies what we might call a “natural death,” and in the latter case the fire practically suffocates. The fire in the open fireplace, if it has plenty of air, will burn up everything burnable that it can reach. The stones of the fireplace or other parts of a stove will not burn, because they have already been burned, and you cannot burn anything a second time, if all of the oxygen in it was burned out of it the first time.

Now, then, to burn up a thing, you must first start a fire under it, and then keep a constant draft of air playing on it from beneath, or the fire will die out. The more difficult a thing is to burn, the more important it is that you have plenty of draft. If the ashes accumulate under the fire the air cannot go through them in sufficient quantity and the fire will go out. Other things which prevent the current of air from going up through the fire will cause it to go out. That is why we close the lower door of the furnace, to keep the fire from burning out. When we shut off the draft of air from below, the fire in the furnace burns slowly, i. e., it just hangs on, so to speak.

Why Does a Lamp Give a Better Light With the Chimney On?

When a lamp is burning without a chimney it generally smokes. That is because the oil which is coming up through the wick is being only partially burned. The carbon, which is about one-half of what the oil contains, is not being burned at all, and goes off into the air in little black specks with the gases which are thrown off. The reason the carbon is not burned when the chimney is off is that there is not sufficient oxygen from the air combining with it, as it is separated from the oil in the partial combustion that is going on. To make the carbon in the oil burn you must mix it with plenty of oxygen at a certain temperature, and this can only be done by forcing sufficient oxygen through the flame to bring the heat of the flame to the point where the carbon will combine with it and burn. When you put the chimney on the lamp you create a draft which forces more oxygen through the flame, brings the heat up to the proper temperature and enables the carbon to combine with it and burn. When you take the chimney off again the heat goes down, when the draft is shut off and the lamp smokes again.

The chimney also protects the flame of the lamp from drafts from the sides and above, and helps to make a brighter light, because a steady light is brighter than a flickering one.

The draft created by the chimney also forces the gases produced by the burning oil up and away from the flame. Some of these gases have a tendency to put out a light or a fire.

Does Light Weigh Anything?

To get at the answer to this question we must go back to the definition of light. Light is a wave in the ether and contains no particles of matter. It, therefore, does not weigh anything at all.

When men had studied light thoroughly, however, they came to the conclusion that it must have the power of pressure, which, from the standpoint of results, would amount to the same thing as having weight. They reasoned that if you had a perfect balance and let sunlight shine down on one of the sides of the balance, that side should go down under the pressure of light. In their first experiments along this line men failed to show that under such conditions the side of the balance on which the light shone did go

down, but by continuous experiments it was proved finally that the light did exert a sufficient pressure to cause the scales to go down, and in effect this is the same as having weight; but this has been found to be a common property of rays of various kinds, including heat, and we, therefore, do not speak of this quality as weight, but as the power of radiating pressure.

Why Does a Stick Seem to Bend When Put in Water?

When light passes from one medium to another, as for example from glass or water to air, or from air or glass to water, the rays of light change their course, thus making them seem to be bent or broken. The rays of light from the part of the stick in the water take a different direction from the rays from the part which is out of the water, giving the appearance of breaking or bending at the place where the air and water meet. It is, of course, the light rays which are bent and not the object itself.

This bending or changing of the path of light rays is called refraction. If you place a coin in a glass of water so that it may be viewed obliquely, you can apparently see two coins, a small one through the surface of the water and another apparently magnified through the side of the glass.

This is due only to the absolute principle that rays of light change their direction in passing from one thing to another, and on this principle of the rays of light our optical instruments, including the microscope, the telescope, the camera and eyeglasses are based.

What Makes the Stars Twinkle?

I might tell you, just to show how clever I am, that stars do not twinkle at all, and leave you with that for an answer. But since they really do seem to twinkle, and that is what causes your question, I will tell you. As we have already learned in our talks about the stars and the sky in general, the stars are suns which are constantly throwing off light, just as our sun gives us light, and when this light strikes the air which surrounds the earth it meets many objects--little particles of dust and other things always floating about in it. The light comes to us in the form of rays from the stars and some of these rays strike particles of various kinds in the air and are thus interfered with. If you are looking at a lighted window some distance away and there are a lot of boys and girls or men and women running past the window, one after the other, rapidly, it will make the light in the window appear to twinkle. The twinkling is due to the interference which the rays of light encounter while traveling toward the eye.

Why Does an Onion Make the Tears Come?

That is nature’s way of protecting the eyes from the smarting which the onion would cause in your eyes if the tears did not come quickly and overcome the bad effect so produced. Tears are provided for washing the ball of your eyes. Every time you wink a little tear is released from under the eyelid, and the wink spreads it all over the eyeball. This washes down the front of the eyeball and cleanses it of all dust and other things that fly at the eye from the air. Then the tear runs along a little channel, much like a trough, at the lower part of the eye, and out through a little hole in the eye, and in this case the tear is really only an eye-wash. Many things, but more often sadness or injured feelings, start the tears coming so fast from under the eyelid that the little trough at the bottom and the hole in the corner of the eye are too small to hold them or carry them off, so they roll over the edge of the lower eyelid and down the face. These are what we call tears. Among other things that will cause tear-glands to cause an over-supply of eye-wash to come down, are onions. What they give off is very trying to the eyes, and so, just as soon as the something which an onion throws off hits the eyeball, the nerves of the eye telegraph the brain to turn on the tears quickly, and they come in a little deluge and counteract the bad effect of the onion.

The First Missile

~HOW MAN LEARNED TO SHOOT~

A naked savage found himself in the greatest danger. A wild beast, hungry and fierce was about to attack him. Escape was impossible. Retreat was cut off. He must fight for his life--but how?

Should he bite, scratch or kick? Should he strike with his fist? These were the natural defences of his body, but what were they against the teeth, the claws and the tremendous muscles of his enemy? Should he wrench a dead branch from a tree and use it for a club? That would bring him within striking distance to be torn to pieces before he could deal a second blow.

There was but a moment in which to act. Swiftly he seized a jagged fragment of rock from the ground and hurled it with all his force at the blazing eyes before him; then another, and another, until the beast, dazed and bleeding from the unexpected blows, fell back and gave him a chance to escape. He knew that he had saved his life, but there was something else which his dull brain failed to realize.

He had invented arms and ammunition!

In other words, he had needed to strike a harder blow than the blow of his fist, at a greater distance than the length of his arm, and his brain showed him how to do it. After all, what is a modern rifle but a device which man has made with his brain permitting him to strike an enormously hard blow at a wonderful distance? Firearms are really but a more perfect form of stone-throwing, and this early Cave Man took the first step that has led down the ages.

This strange story of a development has been taking place slowly through thousands and thousands of years, so that today you are able to take a swift shot at distant game instead of merely throwing stones.

[Illustration: THE SLING MAN IN ACTION

PRACTICE DEVELOPED SOME WONDERFUL MARKSMEN AMONG THE USERS OF THIS PRIMITIVE WEAPON]

We do not know the name of the man who invented the sling. Possibly he did not even have a name, but in some way he hit upon a scheme for throwing stones farther, harder, and straighter than any of his ancestors.

The men and women in the Cave Colony suddenly found that one bright-eyed young fellow, with a little straighter forehead than the others, was beating them all at hunting. During weeks he had been going away mysteriously, for hours each day. Now, whenever he left the camp he was sure to bring home game, while the other men would straggle back for the most part empty-handed.

Was it witchcraft? They decided to investigate.

Accordingly, one morning several of them followed at a careful distance as he sought the shore of a stream where water-fowl might be found. Parting the leaves, they saw him pick up a pebble from the bank and then to their surprise, take off his girdle of skin and place the stone in its center, holding both ends with his right hand.

Stranger still, he whirled the girdle twice around his head, then released one end so that the leather strip flew out and the stone shot straight at a bird in the water.

The mystery was solved. They had seen the first slingman in action.

The new plan worked with great success, and a little practice made expert marksmen. We know that most of the early races used it for hunting and in war. We find it shown in pictures made many thousands of years ago in ancient Egypt and Assyria. We find it in the Roman Army where the slingman was called a “funditor.”

Surely, too, you remember the story of David and Goliath when the young shepherd “prevailed over the Philistine with a sling and with a stone.”

Yet slings had their drawbacks. A stone slung might kill a bird or even a man, but it was not very effective against big game.

What was wanted was a missile to pierce a thick hide.

Man had begun to make spears for use in a pinch, but would you like to tackle a husky bear or a well-horned stag with only a spear for a weapon?

No more did our undressed ancestors. The invention of the greatly desired arm probably came about in a most curious way.

Long ages ago man had learned to make fire by patiently rubbing two sticks together, or by twirling a round one between his hands with its point resting upon a flat piece of wood.

[Illustration: THE “LONG BOW” IN SHERWOOD FOREST

ONE OF ROBIN HOOD’S FAMOUS BAND ENCOUNTERS A SAVAGE TUSKER AT CLOSE RANGE]

In this way it could be made to smoke, and finally set fire to a tuft of dried moss, from which he might get a flame for cooking. This was such hard work that he bethought him to twist a string of sinew about the upright spindle and cause it to twirl by pulling alternately at the two string ends, as some savage races still do. From this it was a simple step to fasten the ends of the two strings to a bent piece of wood, another great advantage since now but one hand was needed to twirl the spindle, and the other could hold it in place. This was the “bow-drill” which also is used to this day.

But bent wood is apt to be springy. Suppose that while one were bearing on pretty hard with a well-tightened string, in order to bring fire quickly, the point of the spindle should slip from its block. Naturally, it would fly away with some force if the position were just right.

[Illustration: DEER STALKING WITH THE CROSSBOW

THIS COMPACT ARM WITH ITS SMALL BOLT AND GREAT POWER WAS POPULAR WITH MANY SPORTSMEN]

There was one man who stopped short when he lost his spindle, for a red-hot idea shot suddenly through his brain.

Once or twice he chuckled to himself softly. Thereupon he arose and began to experiment. He chose a longer, springier piece of wood, bent it into a bow, and strung it with a longer thong. He placed the end of a straight stick against the thong, drew it strongly back, and released it.

The shaft whizzed away with force enough to delight him, and lo, there was the first Bow-and-Arrow!

Armed with his bow-and-arrow, man now was lord of creation. No longer was it necessary for him to huddle with his fellows in some cave to avoid being eaten by prowling beasts. Instead he went where he would and boldly hunted the fiercest of them. In other words, his brain was beginning to tell, for though his body was still no match for the lion and the bear, he had thought out a way to conquer them.

Also he was better fed with a greater variety of game. And now, free to come and go wherever he might find it, he was able to spread into various lands and so to organize the tribes and nations which at last gave us civilization and history.

A new weapon now came about through warfare. Man has been a savage fighting animal through pretty much all his history, but while he tried to kill the other fellow, he objected to being killed himself.

Therefore he took to wearing armor. During the Middle Ages he piled on more and more, until at last one of the knights could hardly walk, and it took a strong horse to carry him. When such a one fell, he went over with a crash like a tin-peddler’s wagon, and had to be picked up again by some of his men. Such armor would turn most of the arrows. Hence invention got at work again and produced the Crossbow and its bolt. We have already learned how the tough skin of animals brought about the bow; now we see that man’s artificial iron skin caused the invention of the crossbow.

What was the Crossbow? It was the first real hand-shooting machine. It was another big step toward the day of the rifle. The idea was simple enough. Wooden bows had already been made as strong as the strongest man could pull, and they wished for still stronger ones--steel ones. How could they pull them? At first they mounted them upon a wooden frame and rested one end on the shoulder for a brace. Then they took to pressing the other end against the ground, and using both hands. Next, it was a bright idea to put a stirrup on this end, in order to hold it with the foot.

Still they were not satisfied. “Stronger, stronger!” they clamored; “give us bows which will kill the enemy farther away than he can shoot at us! If we cannot set such bows with both arms let us try our backs!” So they fastened “belt-claws” to their stout girdles and tugged the bow strings into place with their back and leg muscles.

Who First Discovered the Power of Gunpowder?

Probably the Chinese, although all authorities do not agree. Strange, is it not, that a race still using crossbows in its army should have known of explosives long before the Christian Era, and perhaps as far back as the time of Moses? Here is a passage from their ancient Gentoo Code of Laws: “The magistrate shall not make war with any deceitful machine, or with poisoned weapons, or with cannons or guns, or any kind of firearms.” But China might as well have been Mars before the age of travel. Our civilization had to work out the problem for itself.

It all began through playing with fire. It was desired to throw fire on an enemy’s buildings, or his ships, and so destroy them.

Burning torches were thrown by machines, made of cords and springs, over a city wall, and it became a great study to find the best burning compound with which to cover these torches. One was needed which would blaze with a great flame and was hard to put out.

Hence the early chemists made all possible mixtures of pitch, resin, naphtha, sulphur, saltpeter, etc.; “Greek fire” was one of the most famous.

Many of these were made in the monasteries. The monks were pretty much the only people in those days with time for study, and two of these shaven-headed scientists now had a chance to enter history. Roger Bacon was the first. One night he was working his diabolical mixture in the stone-walled laboratory, and watched, by the flickering lights, the progress of a certain interesting combination for which he had used pure instead of impure saltpeter.

Suddenly there was an explosion, shattering the chemical apparatus and probably alarming the whole building. That explosion proved the new combination was not fitted for use as a thrown fire; it also showed the existence of terrible forces far beyond the power of all bow-springs, even those made of steel.

Roger Bacon thus discovered what was practically gunpowder, as far back as the thirteenth century, and left writings in which he recorded mixing 11.2 parts of the saltpeter, 29.4 of charcoal, and 29 of sulphur. This was the formula developed as the result of his investigations.

Berthold Schwartz, a monk of Freiburg, studied Bacon’s works and carried on dangerous experiments of his own, so that he is ranked with Bacon for the honor. He was also the first one to rouse the interest of Europe in the great discovery.

[Illustration: THE “KENTUCKY RIFLE” WITH ITS FLINT-LOCK WAS ACCURATE BUT MUST BE MUZZLE-CHARGED]

~THE FIRST REAL FIRE ARMS~

And then began the first crude, clumsy efforts at gunmaking. Firearms were born.

Hand bombards and culverins were among the early types. Some of these were so heavy that a forked support had to be driven into the ground, and two men were needed, one to hold and aim, the other to prime and fire.

Improvements kept coming, however. Guns were lightened and bettered in shape. Somebody thought of putting a flash pan, for the powder, by the side of the touch-hole, and now it was decided to fasten the slow-match in a movable cock upon the barrel, and ignite it with a trigger. These matches were fuses of some slow-burning fiber, like tow, which would keep a spark for a considerable time. Formerly they had to be carried separately, but the new arrangement was a great convenience and made the match-lock. The cock, being curved like a snake, was called the “serpentine.”

About the time sportsmen were through wondering at the convenience of the match-lock, they began to realize its inconvenience. They found that they burned up a great deal of fuse, and were hard to keep lighted. Both statements were true, so inventors racked their brains again for something better. They all knew you could bring sparks with flint and steel, and that seemed an idea worth working on. A Nuremberg inventor, in 1515, hit on the wheel-lock. In this a notched steel wheel was wound up with a key like a clock. Flint or pyrite was held against the jagged edge of the wheel by the pressure of the serpentine. You pulled the trigger, then “whirr,” the wheel revolved, a stream of sparks flew off into the flash-pan, and the gun was discharged.

[Illustration: WHEEL-LOCK RIFLE]

This gun worked beautifully, but it was expensive. Wealthy sportsmen could afford them, and so for the first time firearms began to be used for hunting. Some of these sixteenth and seventeenth century nabobs had such guns of beautiful workmanship, so wrought and carved and inlaid, that they must have cost a small fortune. You will find them in many large museums to this day.

But now the robbers had their turn. There are two stories of the invention of the flint-lock. Both deal with robbers, both have good authority, and both may be true, for inventions sometimes are made independently in different places.

One story runs that the flint-lock which was often styled “Lock à la Miquelet,” from the Spanish word, “Miquelitos”--marauders--told its origin in its name. The other is, that the flint-lock was invented in Holland by gangs of thieves, whose principal business was to steal poultry.

In either case the explanation is easy. The match-lock showed its fire at night and wouldn’t do for thieves, the wheel-lock was too expensive, so again necessity became the mother of a far-reaching invention.

Everybody knows what the flint-lock was like. You simply fastened a flake of flint in the cock and snapped it against a steel plate. This struck off sparks which fell into the flash-pan and fired the charge.

It was so practical that it became the form of gun for all uses; thus gunmaking began to be a big industry. Invented early in the seventeenth century, it was used by the hunters and soldiers of the next two hundred years. Old people remember when flint-locks were plentiful everywhere. In fact, they are still being manufactured and are sold in some parts of Africa and the Orient. One factory in Birmingham, England, is said to produce about twelve hundred weekly, and Belgium shares in their manufacture. Some of the Arabs use them to this day in the form of strange-looking guns with long, slender muzzles and very light, curved stocks.

There were freak inventors in the flint-lock period just as there are to-day. Some of them wrestled with the problem of repeating guns, and put together a number of barrels, even seven in the case of one carbine. Others tried revolving chambers, like our revolvers, and still others, magazine stocks. Pistols came into use in many interesting shapes, but these were too practical to be considered freaks.

~WHY WE CALL THEM PISTOLS~

Pistols, by the way, are named from the town of Pistola, Italy, where they are said to have been invented and first used.

We must not forget that rifling was invented about the time that the wheel-lock appeared, and had a great deal to do with the improvement of shooting. Austrians claim its invention for Casper Zollner, of Vienna, who cut straight grooves in the barrel’s bore. His gun is said to have been used for the first time in 1498, but the Italians seem to have still better warrant as these significant words appear in old Latin Italian, under date of July 28th, 1476, in the inventory of the fortress of Guastalla: “Also one iron gun made with a twist like a snail shell.” The rifling made the bullet spin like a top as it flew through the air, thus greatly improving its precision.

In the year 1807 the Rev. Alexander John Forsythe, LL.D., got his patent papers for something far better than even the steady old flint. He had invented the percussion system. In some form this has been used ever since. Which is to say that when the hammer of your gun falls, it doesn’t explode the powder, although it seems to. Instead it sets off a tiny portion of a very sensitive chemical compound called the “primer,” and the explosion of this “primer” makes the powder go off. Of course, the two explosions come so swiftly that your ear hears only a single bang.

Primers were tried in different forms called “detonators,” but the familiar little copper cap was the most popular. No need to describe them. Millions are still made to be used on old-fashioned nipple guns, even in this day of fixed ammunition.

But now we come to another great development, the Breech-loader.

[Illustration: THE MODERN AUTOMATIC RIFLE

THE MODERN SPORTSMAN WITH HIS AUTOMATIC RIFLE IS PREPARED FOR ALL EMERGENCIES]

Perhaps you have had to handle an old muzzle-loader. It was all right so long as you knew of nothing better, but think of it now that you have your beautiful breech-loader. Do you remember how sometimes you overloaded, and the kick made your shoulder lame for a week? Or how, when you were excited you shot away your ramrod? The gun fouled too, and was hard to clean, the nipples broke off, the caps split, and the breeches rusted so that you had to take them to a gunsmith. Yes, in spite of the game it got, it was a lot of trouble, now you come to think of it. How different it all is now!

[Illustration: ASSEMBLING REPEATING SHOTGUNS AND RIFLES]

Breech-loaders were hardly new. King Henry VIII of England, he of the many wives, had a match-lock arquebus of this type dated 1537. Henry IV of France even invented one for his army, and others worked a little on the idea from time to time. But it wasn't until fixed ammunition came into use that the breech-loader really came to stay--and that was only the other day. You remember that the Civil War began with muzzle-loaders and ended with breech-loaders.

[Illustration: ASSEMBLING AUTO SHOTGUNS]

[Illustration: SOME OF THE SHOOTING TESTS]

Houiller, the French gunsmith, hit on the great idea of the cartridge. If you were going to use powder, ball and percussion primer to get your game, why not put them all into a neat, handy, gas-tight case?

THE FIRST AMERICAN MADE GUNS

~HOW THE FIRST AMERICAN GUN WAS MADE~

Two men, a smith and his son, both named Eliphalet Remington, in 1816, were working busily one day at their forge in beautiful Ilion Gorge, when, so tradition says, the son asked his father for money to buy a rifle, and met with a refusal. The request was natural for the surrounding hills were full of game. The father must have had his own reasons for refusing, but it started the manufacture of guns in America.

Eliphalet, Jr., closed his firm jaws tightly, and began collecting scrap iron on his own account. This he welded skillfully into a gun-barrel, walked fifteen miles to Utica to have it rifled, and finally had a weapon of which he might well be proud.

[Illustration: TYPES OF CARTRIDGES]

In reality, it was such a very good gun that soon the neighbors ordered others like it, and before long the Remington forge found itself hard at work to meet the increasing demand. Several times each week the stalwart young manufacturer packed a load of gun-barrels upon his back, and tramped all the way to Utica where a gunsmith rifled and finished them. At this time there were no real gun-factories in America, although gunsmiths were located in most of the larger towns. All gun-barrels were imported from England or Europe.

A VISIT TO A CARTRIDGE FACTORY

~HOW AMMUNITION IS MADE~

One of the first shocks you get when you start your visit through a cartridge factory is the matter-of-fact way in which the operatives, girls in many cases, handle the most terrible compounds. We stop, for example, where they are making primers to go in the head of your loaded shell, in order that it may not miss fire when the bunch of quail whirrs suddenly into the air from the sheltering grasses. That grayish pasty mass is wet fulminate of mercury. Suppose it should dry a trifle too rapidly. It would be the last thing you ever did suppose, for there is force enough in that double handful to blow its surroundings into fragments. You edge away a little, and no wonder, but the girl who handles it shows no fear as she deftly but carefully presses it into moulds which separate it into the proper sizes for primers. She knows that in its present moist condition it cannot explode.

[Illustration: INSPECTING METALLIC SHELLS]

[Illustration: EXAMINING PAPER SHELLS]

[Illustration: WEIGHING BULLETS]

Or, perhaps, we may be watching one of the many loading machines. There is a certain suggestiveness in the way the machines are separated by partitions. The man in charge takes a small carrier of powder from a case in the outside wall and shuts the door, then carefully empties it into the reservoir of his machine, and watches alertly while it packs the proper portions into the waiting shells. He looks like a careful man, and needs to be. You do not stand too close.

[Illustration: SHOOTING ROOM OF BALLISTICS DEPARTMENT]

[Illustration: CHRONOGRAPH FOR MEASURING]

The empty carrier then passes through a little door at the side of the building, and drops into the yawning mouth of an automatic tube. In the twinkling of an eye it appears in front of the operator in one of the distributing stations, where it is refilled, and returned to its proper loading machine, in order to keep the machine going at a perfectly uniform rate; while at the same time it allows but a minimum amount of powder to remain in the building at any moment. Each machine has but just sufficient powder in its hopper to run until a new supply can reach it. Greater precaution than this cannot be imagined, illustrating as it does that no effort has been spared to protect the lives of the operators.

[Illustration: PUTTING METAL HEADS ON PAPER SHOT SHELLS]

It is remarkable that, in an output of something like four million per day, every cartridge is perfect.

Such things are not accidental. The secret is, inspection.

~TESTING MATERIALS AND PRODUCTS~

Let us see what that means. It means laboratory tests to start with. Here are brought many samples of the body paper, wad paper, metals, waterproofing mixture, fulminate of mercury, sulphur, chlorate of potash, antimony sulphide, powder, wax, and other ingredients, and even the operating materials such as coal, grease, oil, and soaps. In the laboratory we see expert chemists and metallurgists with their test-tubes, scales, Bunsen burners, retorts, tensile machines, microscopes, and other scientific looking apparatus, busily hunting for defects.

For example, one marker is examining a supply of cupro-nickel, such as is used in jacketing certain bullets. A corner of each strip is first bent over at right angles, then back in the other direction until it is doubled, then straightened. It does not show the slightest sign of breaking or cracking, in spite of the severe treatment, therefore it is perfect. Let but the least flaw appear, and the shipment is rejected.

[Illustration: WHAT A SHOT TOWER LOOKS LIKE

SHOT TOWER--TALLEST BUILDING IN CONNECTICUT]

[Illustration:

LARGEST CARTRIDGE EQUALS MORE THAN 1,000,000 OF SMALLEST (HELD ON HAND)]

Two large iron cylinders descend in the center, coming down through the ceiling from above; we are invited to look through an open port in one of these.

We see nothing but the whitened opposite wall, against which a light burns.

It appears absolutely empty, though within it is raining such a swift shower of invisible metal that if we were to stretch our hands into the apparently vacant space they would be torn from our arms.

A large water tank below is churned into foam with the impact of the falling shot, and as we look downward we make out finally the haze of motion. It is so interesting that we take the elevator and rise ten stories to the source of the shower.

Here high in the air are the large caldrons where many pigs of lead, with the proper alloy, are melted into a sort of metallic soup. This is fed into small compartments containing sieves or screens, through the meshes of which the shining drops appear and then plunge swiftly downward.

But this only begins the process. Taken from the water tanks and hoisted up again, the shot pellets, in a second journey down, through complicated devices, are sorted, tumbled, polished, graded, coated with graphite, and finally stored.

The pictures shown in this story were prepared especially to illustrate this story of “How Man Learned to Shoot” by the Searchlight Library for the Remington Arms Company.

The Parts of a Big Gun

~THINGS TO KNOW ABOUT A BIG GUN~

Before going into a description of the manufacture of a big gun it would be well to understand the following definitions:

The “breech” of a gun is its rear-end, or that end into which the projectile and powder charge are loaded.

The “muzzle” of a gun is its forward end.

By “calibre” is meant the inside diameter of the gun in inches. A 5-inch gun is one of “minor calibre,” and one of 14-inches a gun of “major calibre.”

The length of a gun is never expressed in inches or feet, but in the _number of times_ that its calibre is divisible into its length; thus, when we say a 12-inch 50-calibre gun, we mean a gun of 12 inches in diameter, and 12 times 50, or 600 inches long.

The “bore” is the hole extending through the center of the gun, from the rear face of the liner to its forward end.

The “powder chamber” is the rear part of the bore, and extends from the face of the breech plug when closed to the point where the “rifling” begins. The powder chamber is slightly larger in diameter than the rest of the bore.

The “rifling” is the name given to the spiral grooves which are cut into the surface of the bore of the gun, and give to the projectile its rotary motion when the gun is fired.

With the advent of “iron-clads” and heavily armored fortresses, it became necessary to increase the power of the guns in use, until to-day a 14-inch gun of 45 calibres fires a projectile weighing 1400 pounds, with an initial velocity of 2600 feet per second. An idea of this initial velocity may be better obtained by comparison when you realize that a train going sixty miles an hour is only traveling at the rate of 88 feet per second. Now, in order to produce such wonderful power in a gun, great pressure must be generated in the bore, and it was soon found that a one-piece gun, whether cast or forged, could not withstand such pressures.

To begin with, we may consider this one-piece gun, or any gun, as a tube which must withstand a great pressure from within, so that when a gun is designed care must be taken to see that the material from which it is constructed is strong enough to withstand this pressure. And not only must the gun be sufficiently strong, but it must not be too heavy, so that you see you cannot go on forever increasing the thickness of the walls of this tube. Besides, it is generally acknowledged that a simple tube or cylinder cannot be made with walls of sufficient thickness to withstand from within a _continued_ pressure per square inch greater than the tenacity of a square-inch bar of the same material; in other words, if the tensile strength of a metal is only twelve tons per square inch, no gun of that metal, however thick its walls, could withstand a pressure of twenty tons per square inch, and the modern big guns are tested at that great a pressure. And if we look further into this matter of pressures we find that when a gun is fired the pressure exerts itself in two ways; it tends to burst the gun longitudinally or down the middle, and it tends to pull the gun apart in the direction of its length. Of course, some method of strengthening this one-piece gun was sought after, with the result that to-day guns are either “_built-up_” or “_wire-wound_.”

A “built-up” gun is one made of several layers, each layer being separately constructed and then assembled together. The order of assemblage differs somewhat with the different calibres, but the method of assemblage is essentially the same, that is, the outside layers are heated and shrunk on the inner ones. This question will be treated at greater length later on.

A “wire-wound” gun is one in which the necessary additional strength is obtained by winding wire around an inner tube of steel, each layer being wound with a different tension of the wire; this type of gun has found great favor with foreign manufacturers. In this country, however, the “built-up” system is used almost exclusively, and so this description will deal with the manufacture of a “built-up” gun.

[Illustration: HOW A BIG GUN WOULD LOOK IF YOU WERE TO CUT IT IN TWO

Sketch Showing Construction of a Modern “Built-up” Gun.

_A_, HOOP; _B_, HOOP; _C_, JACKET; _D_, TUBE; _E_, LINER; _F_, HOOP.]

A modern “built-up” gun is composed of a _liner_, a _tube_, a _jacket_ and _hoops_.

The _liner_ is in one piece and extends the entire length of the bore and carries the “rifling” and the powder chamber.

The _tube_ is in one piece and envelops the liner for its entire length. Formerly the _tube_ carried the “rifling” and powder chamber, but due to the wearing out of the “rifling” with constant firing, a liner was decided on, so that now when the “rifling” becomes worn, the liner can be removed and a new one substituted.

The _jacket_ is usually in two pieces and is shrunk on the tube; it extends the entire length, and its rear end is threaded in the inside for the attachment of the “breech bushing.”

Hoops are shrunk on over the jacket and in a big gun are sometimes as many as six or seven in number.

The liner, tube, jacket and hoops are made of the finest quality of open hearth steel, and the steel must conform to specifications set by the government.

[Illustration:

Photo by Bethlehem Steel Co.

This photograph shows a mould for a gun ingot under hydraulic press for fluid compression.]

The chemical composition having been determined, the necessary elements are weighed out and the whole charged into an open hearth furnace. When the furnace is ready to be tapped the molten metal is run into a large ladle, which in turn is taken by a crane to the casting pit, where the mould is filled. The ingots for the large calibre guns run from 42-inch to 48-inch in diameter, and after being poured they are immediately run under a hydraulic press, where they are subjected to a pressure of about six tons per square inch to drive out the gases, and then lowered to about 1500 pounds pressure per square inch for a certain length of time during the cooling. This pressure tends to make the ingot solid, by expelling the gases, which would cause blow-holes, and by preventing “piping” and “segregation.” When a metal cools, the top and sides cool first, and this outer layer shrinks and pulls away from the centre, with the result that a cavity or “pipe” would be formed, but the hydraulic pressure forces fluid metal into this cavity and so prevents the “pipe.” The cooling also causes the various elements to solidify separately, and they tend to break away from the mass and collect at the centre; this is called “segregation,” and is also partially prevented by fluid compression. A solid ingot, however, is obtained, and this is absolutely necessary.

After the ingot has cooled sufficiently it is “_stripped_,” that is, it is removed from the mould, and then it is sent to the shop to have the “discard,” or extra length, cut off. When the ingot is cast, an extra amount of metal is poured into the mould to permit this discard, the theory being that the poorer metal, together with gases and other impurities, rise to the top. The government specifications require that there shall be a 20% discard from the upper end and a 3% discard from the lower end. The discard having been cut off, the ingot is “cored,” that is, its centre is bored out, the diameter of the hole depending on the size of the ingot.

[Illustration: TAKING THE BORE OF A BIG GUN

Photo by Bethlehem Steel Co.

This photograph shows gun ingot in boring mill being cored.]

The ingot is now ready for the “forge,” and on its receipt in the forge shop it is placed in a furnace to be heated; and here great care must be exercised to prevent setting up any additional strains in the ingot. When the ingot was cooling just after casting the metal tended to flow from the centre; the interior is still in a condition of strain, and if the cold ingot is now placed in a hot furnace, cracks

are apt to form in the centre, causing the forging to later break in service.

However, the ingot having been properly heated, it is ready for either the forging hammer or the press. The present-day practice, though, is to forge the ingot under a press forge, as the working of the metal causes a certain flow, and as a certain amount of time is necessary for this flow, the continued pressure and slow motion of the press allows the molecules of the metal to adjust themselves more easily, and a better and more homogeneous forged ingot is produced than if the forging had been done with a hammer.

When forging a hollow ingot, a mandrel, merely a cylindrical steel shaft, is placed through the hole in the ingot and the ingot forged on the mandrel, thereby not only is the outside diameter of the ingot decreased, but the length of the ingot is increased. The usual practice is to continue the forging until the original thickness of the walls of the ingot is decreased one-half and until the ingot is within two inches of the required finished diameters. The ingot is now known as a “forging,” and the lower end of each ingot as cast will be the breech end of the forging that is made from it.

The next process is that of “annealing.” This consists in heating the forging to a red heat and then allowing it to cool very slowly, and is usually done by hauling the fires in the furnace after the correct temperature has been attained and permitting both to cool off together. This process is to relieve the strains set up in the metal during forging, and further, it alters the molecular condition of the steel, making a finer and more homogeneous forging.

[Illustration: HOW THE GUN TUBE IS TEMPERED

Photo by Bethlehem Steel Co.

This photograph shows a gun tube ready to be lowered into oil bath for “oil tempering.”]

After annealing, the forging is ready to go to the machine shop to be rough bored and turned. The forging is set in a lathe, the breech end being held by jaws on the face-plate and the muzzle end by a “pot-centre,” a large iron ring having several radial arms screwed through it. The lathe can now be turned and the forging centered by screwing in or out on the jaws of the face-plate or the radial arms of the “pot-centre.” When centered, several surfaces are turned on the forging for “steady rests” and then all is in readiness for the turning and boring.

In both operations of “turning” and “boring,” the work revolves while the cutting tools are fed along. Turning is very simple and usually several tools are cutting at the same time, but boring is a more delicate operation, because the workman cannot see what he is doing. And in boring, either a “hog bit” or a “packed bit” is used; a “hog bit” is a half cylinder of cast iron fitted with one cutting tool and used for rough cuts, while a “packed bit” is a full cylinder of wood with metal framing and carrying two tools 180° apart and used for finishing cuts.

The forging, having been rough machined, is now ready to receive its heat treatment in order to give to the steel its required physical characteristics. Every piece of steel used in gun manufacture must conform to certain specifications as regard both its physical and chemical characteristics. The chemical analysis was made at the time the ingot was cast; now for the treatment of the forging, prior to the physical test as to its tensile strength, elastic limit, elongation and contraction.

The “tensile strength” of a metal is the unit-stress required to break that metal into parts. If a round bar ten inches in cross-section area will fracture under a strain of 120 tons, its tensile strength is 120 ÷ 10 or 12 tons per square inch. Tensile strength is usually expressed in pounds per square inch.

The “elastic limit” of a metal is the unit-stress required to first produce a permanent deformation of the metal. If a bar of metal be subjected to an increasing strain, up to a certain point that metal will be perfectly elastic, resuming its normal shape when the strain is removed; at the first permanent set or deformation, however, the elastic limit of that metal has been reached. Elastic limit is expressed in pounds per square inch.

By “elongation” is meant the increase in length in a bar when its tensile strength is reached. If a bar 10 inches long after rupture measures 11.8 inches, its elongation is 18%.

By “contraction” is meant the decrease in cross-section area in a bar when its tensile strength is reached. If a bar 1 square inch in area after rupture is only .75 of a square inch in area, its contraction is 25%.

These definitions being understood, a brief description of the heat treatment can be taken up, because it is after this treatment that standard bars are taken from the forgings to undergo the physical tests. The first step consists in “tempering” or hardening the metal. The piece to be tempered is placed in an upright position in a high furnace and uniformly heated to the required temperature. It is then lifted from the furnace through an opening in the top and carried by a crane to an oil tank of suitable depth and plunged into the oil. This rapid cooling or “tempering in oil” is facilitated by having the oil tank surrounded by a water bath, so arranged that a supply of cold water is constantly in circulation to carry the heat from the mass as quickly as possible. This operation produces exceeding toughness, increases the tensile strength and raises the elastic limit of the metal.

Now the forging is again annealed, so as to relieve any strains set up by tempering and to soften up the metal to the degree required by the specifications. It also increases materially the elongation and contraction. Great care must be exercised in the heat treatment, as the acceptance or rejection of the forging depends upon whether or not the test bars pass the required specifications.

The forging is now submitted for test and the test bars taken. In the manufacture of a big gun, four test bars are taken from the breech end and four from the muzzle end of each forging and these bars sent to the physical laboratory. Quite an elaborate testing machine is provided, and if the bars pass the required tests the forging is accepted and is sent to the machine shop for finish-boring and turning.

~SEARCHING FOR POSSIBLE DEFECTS~

Frequently during finish-boring the work is examined to see that the bit is running true, and great care must be exercised to prevent its running out of alignment.

After finish-boring every forging is “bore-searched,” that is, the bore is carefully examined for any cracks, flaws, streaks or discoloration. A special instrument called a “bore-searcher” is used and consists of a long wooden handle which has a mirror inclined at 45° at one end, together with a light to illuminate the bore, and so shielded as to obscure the light from the observer. (See sketch.)

[Illustration]

The bore is also inspected by the foreman after each boring, but the final “bore-searching” is done by an inspector.

Now to measure accurately the inside diameters of long cylinders, such as are used in gun work, a special measuring device called a “star-gauge” is used. Its name is derived from the fact that it has three measuring points set at 120° apart and two measurements are taken, one [Illustration] and the other [Illustration], making a star [Illustration]. Every forging is “star-gauged” after being finish-bored and also the liner of the _gun_ after each assemblage operation.

~PUTTING THE PARTS OF A “BUILT-UP” GUN TOGETHER~

In preparation for the assembling of the different parts, the tube is the forging to be finished. It is bored and turned to exact dimensions and carefully “bore-searched” and “star-gauged.” With the data at hand a sketch is made showing the external diameters of the liner under the tube, due allowance being made for the shrinkage when assembling.

The liner is next bored to within .35 of an inch of the finished diameter, and turned to the dimensions required by the sketch above. This extra metal in the bore is left until the gun is completely assembled and is removed in the finish-boring. The liner is then carefully “bore-searched” and “star-gauged” and liner and tube are ready for assembling.

The liner is now taken to the shrinking pit and carefully aligned in an upright position with the breech end down.

The shrinking pit is merely a well of square section with room enough to permit workmen to move freely about the gun when it is in position, and equipped with a movable table at its bottom upon which the gun rests. In the meantime the tube, with breech end down, is being heated in a hot-air furnace. This furnace is a vertical cylinder built of fire-brick and asbestos and so constructed that air which has been passed in pipes over petroleum burners can enter at the bottom, pass around and through the tube and out through the top to be reheated. This service permits a uniform heat to be transmitted to the tube and when the desired temperature has been attained the tube is lifted from the furnace by a crane, carried to the shrinking pit and carefully lowered over the liner. Great care must be exercised in this operation to prevent the tube from sticking while being lowered into place. Should it happen, the tube should be hoisted off at once, allowed to cool, any roughing of the liner be smoothed off, the tube reheated and a second trial made. When the tube is properly in place a cold spray may be turned upon any particular section where it is desired the tube

should first grip the liner. The tube is then left to cool by itself, but cold water is constantly circulating through the liner.

When the gun is sufficiently cool for handling purposes, it is hoisted out of the shrinking pit and taken to the shop for careful measurement, the liner being “star-gauged” to note the compression due to the shrinking on of the tube.

The same procedure is followed in the case of the jackets and hoops, until the entire gun is assembled. The gun is considered completely “built-up” when the last hoop has been shrunk on and is now ready to be finished.

The gun is now finish-bored, as .35 of an inch of metal was left in the liner in the first boring. “Packed bits” are used and the greatest care is exercised to keep the bit properly centered and running true. After this step the gun is finish-turned and the powder chamber is bored.

Following this operation the gun is “bore-searched” for any defects that may have shown up in the finish-boring and chambering, and then carefully “star-gauged.” The gun is then ready to be “rifled.”

[Illustration: RIFLING A BIG GUN

Photo by Bethlehem Steel Co.

This photograph shows a gun in the Rifling Machine in the process of being rifled.]

The “rifling” of a gun consists in cutting spiral grooves in the surface of the bore from the powder chamber to the muzzle end, and is done from the muzzle end. Rifling is a very difficult operation, and great care must be exercised that the cutting is uniform. The grooves are separated by raised portions called “lands,” and after “rifling,” these grooves and “lands” are carefully smoothed up to remove the rough edges or burrs caused by the cutting tools of the “rifling” machine.

The necessary holes are now drilled for fitting the breech mechanism and the breech block fitted. This operation usually takes some little time, as quite a bit of hand work is necessary to insure a perfect fit. The “yoke,” really another “hoop,” is now put on at the breech end and the gun is complete.

The centre of gravity of gun and breech mechanism is now determined by balancing on knife edges and the whole then weighed. The breech mechanism is also weighed and the two weights marked on the rear faces of the gun and breech mechanism.

The gun is now fitted in its “slide,” that part of the mount which carries the trunnions and through which the gun recoils when it is fired, and after it is adjusted, all is in readiness for the “proof-firing” or testing of the gun.

What Is Motion?

There are practically but two things we see when we use our eyes. One of them is matter, which is a term we apply to the things we see, speaking of them as objects only, and the other is motion which we observe some of the matter to possess. Some of the things we see confuse us, if we bear in mind that everything is either matter or motion. For instance, we see light and know it is not matter and are confused until we understand that light is a movement of the ether which surrounds us and is in and outside of everything. In the same way we feel heat and may think it is matter thrown off by the fire, when it is only another kind of motion of this same ether. When we understand these things we see that motion is a very important and real part of the world.

When a motion is started it will keep on going forever unless some other force which is able to overcome the motion stops it. When a ball is thrown in the air it would go on forever were it not for the law of gravitation which pulls it to the earth and the friction of the air on the ball as it goes through the air. When you stop a thrown ball you sometimes realize that motion is a real thing because it stings your hands. We do wonderful things with motion. Many things when you add motion to them acquire qualities which they did not possess before. For instance, an ordinary icicle thrown against a wooden door will break, but if you put it into a gun and give it sufficient motion, it will go right through the door. There is a story of how a man killed another by using an icicle as a bullet. The icicle entered the man’s body and killed him. Then, of course, the ice melted and no one could tell how the man received his wound, for no trace of anything like a bullet could be found. A piece of paper has no cutting qualities, but if you arrange a circular or square piece of paper with a rod or stick through the center and revolve it fast enough, you can cut many things while it is whirling. The motion gives it the cutting qualities. You can take a piece of strong rope and, by tying the ends together, making a circle of it, you can make it roll down the street like a steel hoop if you catch it just the right way and set it spinning fast enough before starting it on its way. A steam engine has no power to pull the train of cars until the wheels are set in motion. So we see that motion is a

very important thing in the world.

Motion is the cause of movements of all kinds, the power which takes things from one place to another.

Is Perpetual Motion Possible?

Perpetual motion will never be possible unless some one discovers a way to overcome the law of gravitation and also the certainty that materials will eventually wear out. Many men have tried to make a machine that would keep on moving forever without the application of any power, the consumption of fuel within itself, the fall of weights or the unwinding of a spring; such a machine would be absolutely impossible, although many people have been fooled into investing money in machines that appeared to have this power within themselves.

How Can an Explosion Break Windows That Are at a Distance?

An explosion is a sudden expansion of a substance like gunpowder or some elastic fluid or other substance that has the power to explode under certain conditions with force, and usually a loud report. Some explosions are comparatively mild and accompanied by a very mild noise, while others are very powerful and accompanied by a very loud noise. When an explosion occurs, the air and everything surrounding the thing that explodes is very much disturbed. The air surrounding the thing that explodes is thrown back in air waves which are powerful in the exact proportion in which the explosion is powerful. These air waves can be so suddenly thrown back against the objects in the vicinity that not only the windows in the buildings are broken, but often the entire building blown away. The explosion acts in all directions at once with equal force. A great hole may be torn in the earth beneath the explosion. If there is anything over the explosion, that is blown away unless its power of resistance is sufficient to withstand the power of the explosion. Then, also, the air surrounding on all sides is forced back against everything in its path.

Very often this air which is suddenly forced back by the power of the explosion is thrown against houses at a distance. These houses may be so strongly built as to be able to withstand the effect of the explosion, but still certain parts of them, such as the windows and the bricks of the chimney, may not be able to withstand this sudden pressure of air against them and they are forced in. The wind from such an explosion acts on the outside of the windows just the same as though you stood on the outside with your hands against the windows and pushed them in. Anything that is thrown against a window with more force than the window glass can resist will break the window, and even slight explosions may be so powerful as to throw the air back and away from them with such force as to break windows at a great distance--even a mile or more away.

Why Do Some Things Bend and Others Break?

When an outside force is applied to some objects, some of them will bend and others break. It is due to the fact that in some things the particles have the faculty of sticking together or hanging on to each other, and it is very difficult to break them away from each other. In such instances, as in the case of a wire, the article will bend when we apply the power to it and it will not break, because the particles which make up the wire have the faculty of hanging on to each other. A piece of glass, however, can be broken right in two by the application of no more force than was used to bend the wire, because the particles which make up the glass haven’t the faculty to hang on to each other. If you continue to bend a wire back and forth, however, at the same point, it will finally break apart, because you eventually overcome the ability of the particles in the wire to hang on to each other.

It all depends upon the hanging-on ability. Sometimes in undergoing different processes an article which will ordinarily only bend will become very brittle or breakable. A steel wire may bend but if you make a steel wire very hard it becomes brittle. On the other hand, glass is very brittle ordinarily, but if you make it very hot, you can bend it into any shape you wish, and thus the glass-worker makes different shapes to various dishes; lamp chimneys, bottles, etc., by heating glass and then bending it. When it becomes cool again, it also becomes brittle or breakable as before.

Why Does a Ball Bounce?

When you throw a ball against the floor in order to make it bounce the ball gets out of shape as soon as it comes in contact with the floor. As much of it as strikes the floor becomes perfectly flat, and because the ball has a quality known as elasticity, which means the ability to return to its proper shape, it returns to its shape immediately and in doing so forces itself back into the air and that is the bounce.

Of course, the first thing we think of when we consider something that bounces is a ball, and in most cases a rubber ball. We are more familiar with the bouncing qualities of a rubber ball. Other balls, like standard baseballs, are not so elastic as a rubber ball filled with air, but a solid-rubber ball is more elastic and some golf balls are much more elastic than a solid-rubber ball. The principle is the same, when you drive a golf ball, excepting that when you bounce a ball on the floor the floor does the flattening and when you drive a golf ball, the golf club does the flattening. A baseball flies away from the bat for the same reason. When you meet a fast-pitched ball squarely on the nose with a good swing, it goes farther and faster than when you hit a slow-pitched ball with an equal swing, because in the case of the fast-pitched ball you flatten the ball out more, and it has so much more to do to recover its proper shape that it bounces away from the bat at much greater speed and goes much further unless caught than a slow-pitched ball under the same circumstances.

What Makes a Ball Stop Bouncing?

A bouncing ball, when you first throw it against the wall bounces back at you about as fast as you throw it, but if you do not catch it on the rebound, it goes to the floor again, because the law of gravitation which is the pulling power of the earth, pulls it down again. When it strikes the floor it is again flattened to a certain extent and bounces up again, but does not come back so high. It goes on striking the floor and bouncing back into the air again each time a shorter distance, until the force of gravity has actually overcome its tendency to bounce back.

When you bounce a ball on the floor and it bounces up again, the motion of the ball through the air is affected by the friction that the contact with the air produces and this friction of the air overcomes part of the bouncing ability in the ball also.

What Makes a Cold Glass Crack if We Put Hot Water Into It?

Hot water will not always cause a cold glass to crack, but is very apt to, especially a thick glass. The very thin glasses will not crack. The test tubes used by chemists are made of very thin glass, and will not crack when hot liquids are poured into them.

When a glass cracks after you have poured a hot liquid into it, it does so because, as soon as the hot liquid is put in, the particles of glass which form the inside of the glass become heated and expand. They begin to do this before the particles which form the outside of the glass become heated, and in their efforts to expand the inside particles of glass literally break away from the particles which form the outside, causing the crack. The same thing happens if you put cold water into a hot glass, excepting in this instance the inside particles of the glass contract before the particles which form the outside of the glass have had time to become cool and do likewise.

What Causes the Gurgle When I Pour Water from a Bottle?

The air trying to get in causes the gurgle. Air has one strong characteristic which stands out above everything else. It wants to go some place else all the time. When it learns of a place where there is no air it wants to go there above all things, and goes at it with a rush.

Now, when you turn a bottle full of water upside down, the water comes out if the cork is out, of course, and as soon as the water starts out the air strives to get in, and every time you hear a gurgle you know the air is getting in. Every gurgle is a battle between the water and the air. Sometimes the air comes and pushes the water back enough to let it slide into the bottle; sometimes the water pushes the air back, and thus they fight back and forth. The water always gets out and the air always gets in. In doing so they make the gurgle.

Where Does the Part of a Stocking Go That Was Where the Hole Comes?

Perhaps this is a foolish question, but many boys and girls have been puzzled for an answer to it. When you put your stockings on they have no holes in the feet, and at night, when you take them off, there are often quite large holes in them. The answer is the same as in the case of the lead in the lead-pencil. The lead in the pencil wears away. You can see it wear away because that is what makes the marks.

When a hole is coming into your stocking, the stocking on your foot is being rubbed between your foot and something else (probably some part of your shoe) and this constant rubbing will wear through the yarns with which the stocking is knitted. Of

course, the yarns in the stocking are stretched somewhat when it is on your foot and the rubbing finally cuts through the threads and releases the tension of the threads of yarn, so that not always is as much stocking lost as the size of the hole. But, if you were to look carefully at your foot and inside your shoe, when you first take the stocking off and see the hole, you would find little particles of yarn all about.

Why Do Coats Have Buttons On the Sleeves?

The practice of putting buttons on coat sleeves, which serve no useful purpose at all and do not add to the beauty of the coat, is a relic of very old days.

There was a time when people did not use handkerchiefs, and it was common practice for men to wipe their noses on their sleeves. They had coats also in those days, but they did not have buttons on the sleeves. One of the old kings finally developed the idea of dressing his soldiers in fancy uniforms and, as he sat in his palace and reviewed his troops, he noticed many of them using the sleeves of their coats as handkerchiefs. He immediately issued a decree that all sleeves should have a row of buttons sewed on them, but at a point directly opposite to where they are now on the sleeves. This was done to remind the soldiers that the sleeves of their beautiful uniforms were not to be used as handkerchiefs, and those who attempted to draw their sleeves in front of the nose were quickly reminded of the decree by the buttons which scratched them. And so the buttons really had a quite useful purpose at one time, and so also all sleeves had buttons sewed on to them at this place. Later on, however, when the unsightly practice had been cured and people had learned to use handkerchiefs, the buttons remained as a decoration, but their former purpose was lost sight of. Then some tailor or leader of fashion had the buttons set on the under side of the sleeves for a change, and it became the fashion to have them there, and the tailors have been sewing them there ever since.

Why Has a Long Coat Buttons on the Back?

The buttons on the back of a long coat, i. e., one with skirts, had a more sensible reason originally. At one time the skirts of such coats were made very long, and when the wearer moved quickly the tails of the coat flapped about the legs and interfered with progress. So an ingenious gentleman had buttons sewed on to the back and buttonholes made in the corner of his coat-tails. Then when he was in a hurry he simply buttoned up his skirts and went his way comfortably.

[Illustration: TELEPHONE DISPLAY BOARD

Showing in outline the apparatus necessary to complete the simplest kind of a telephone call--to a number in the same exchange]

The Story in the Telephone

~WHAT HAPPENS WHEN WE TELEPHONE~

Mrs. Smith, at “Subscriber’s Station No. 1,” desires to telephone to Mrs. Jones at “Subscriber’s Station No. 2.” When she lifts her receiver, the movement causes a tiny white light to appear instantly on the switchboard at the Central Office. Directly beneath this light is another and larger lamp, which glows in a way to attract the operator’s attention immediately.

The operator inserts a “plug” in a little hole on the switchboard called a “jack,” directly above the tiny light which appeared when Mrs. Smith lifted the receiver. This connects her to Mrs. Smith’s line. Then she pushes a listening key on the board, connecting her telephone set to the line. “Number, please?” she calls.

Mrs. Smith gives the number; the operator repeats it to be sure there is no mistake, places another “plug” in a “jack” corresponding to the number of Mrs. Jones’ telephone and makes the connection.

Each subscriber’s telephone has a particular signal on the switchboard to which it is connected by a pair of wires. Mrs. Smith’s wires run from her instrument to the nearest “cable terminal,” a gathering point for the wires of various telephones in her neighborhood. Here they form part of a group of wires going to the Central Office. These groups, called cables, are made up of from 50 to 600 pairs of wires, according to the telephone needs of the district the “terminal” serves.

When the wires reach the Central Office they pass through the “cable vault” to the “main distributing frame,” which is the Central Office terminal of the cable.

When the wires come to this frame they are in numbered order in the cable. Subscribers living next door to Mrs. Smith may have entirely different call numbers and yet use consecutive wires. It is the task of the main frame to redistribute these wires, so that they will be arranged according to their call numbers and to make it possible to connect Mrs. Smith's line with the line of any other subscriber with the least possible delay. This frame has two parts: the "vertical side" and the "horizontal side." Before the wires are redistributed they are taken to pairs of springs equipped with devices for protecting the lines against outside currents.

[Illustration: ASKING FOR A NUMBER]

After leaving the main frame they are taken to the "intermediate distributing frame," the central connecting point for various branches of the lines going to the switchboard, signaling and other apparatus. From the "horizontal side" of this frame, wires go to the switchboard, where they terminate in little holes known as "multiple jacks." They also connect with the line and position message registers, where the calls from each Line and the calls handled at each operator's position at the switchboard are recorded. The "multiple jacks" are additional terminals placed at necessary intervals throughout the switchboard, where they can be used by operators to make connections with any other line on the board.

From the "vertical side" of the intermediate frame Mrs. Smith's wires reach the "line and cut-off relay," an electrically controlled switch which turns on the light signal that appears on the switchboard when she lifts the receiver from the hook. This "line relay" also extinguishes the light when the operator makes the connection, or when Mrs. Smith returns the receiver to the hook.

[Illustration: A TYPICAL POLE LINE, WITH CROSS ARMS, IN THE COUNTRY]

The swift moving electric current that was set in motion when Mrs. Smith began the call, instantaneously passes through all these devices for safeguarding and protecting the subscriber's telephone service. The light announcing Mrs. Smith's desire to make a call is called the "line lamp," and is flashing on the switchboard. Directly beneath it is the "pilot lamp," which glows whenever any "line lamp" lights. With the "line lamp" is a "jack" or terminal, where connection can be made with Mrs. Smith's line. This is the "answering jack."

[Illustration: THE CABLE VAULT INTO WHICH THE CABLES PASS WHEN THEY ENTER THE EXCHANGE AND FROM WHICH THEY ARE LED UPWARD TO THE MAIN DISTRIBUTING FRAME]

When the operator sees the flashing signal of Mrs. Smith's "line lamp," she inserts one end of a pair of "connecting cords," which are on the board before her, in the "answering jack" for Mrs. Smith's line. These "connecting cords" are flexible conductors that put the wires of subscribers in electrical connection. Then she pushes forward the "operator's key" directly in front of her and is connected with Mrs. Smith's line.

The operator ascertains the number wanted and places the other "connecting cord" in the "jack" corresponding to Mrs. Jones' line. If she finds she cannot herself connect with Mrs. Jones' "jack," because it is on another part of the board out of her reach, she makes a connection with another operator who can reach Mrs. Jones' line. The second operator then makes the connection with Mrs. Jones' "multiple jack" and places her line in connection with Mrs. Smith's line at the first operator's position. At the same time the first operator pushes the operator's key back, thus ringing Mrs. Jones' bell.

"Supervisory lamps" on the board before her, connected with the "connecting cords," tell the operator when Mrs. Jones answers the summons. They flash when the connection is made and one goes out just as soon as Mrs. Jones takes the receiver from the hook to answer. If one of these lamps flashes and dies out alternately it tells the operator that either Mrs. Smith or Mrs. Jones is trying to attract her attention and she connects herself and ascertains the party's wishes. When both subscribers "hang up," both lights flash to indicate the end of the conversation. The operator then disconnects the cords from the subscribers' "jacks" and presses the "message register" button recording the call against Mrs. Smith.

[Illustration: ROUTINE OF A TELEPHONE CALL

The subscriber, after looking up in the directory the desired number, takes the telephone off the hook, which causes a tiny electric light to glow in front of the operator assigned to answer his calls. (In some exchanges equipped with a magneto system, a drop is released by the turning of a crank.)]

[Illustration: The arrow indicates the light as it appears on the switchboard. Each operator can connect a caller with any subscriber in that exchange, but she is assigned to answer the calls of only a limited number of subscribers whose signals are these lights showing at her particular position.]

[Illustration: She takes up a brass-tipped cord, inserts the tip, or “plug,” into the hole, or “jack,” just above the light, at the same time throwing a key with the other hand in order to switch her transmitter line into direct communication with the caller, and says: “Number?”]

[Illustration: The caller replies by giving the name of the exchange and the number he wants, as for example, “Main 1268.” The operator repeats the number, “One-two-six-eight,” pronouncing each digit with clear articulation, to insure its correctness, and, if it be from a subscriber in the Main Exchange, she--]

[Illustration: Takes up the cord which is the team mate, or “pair,” of the one with which she answered the caller, locates the jack numbered 1268, and “tests” the line by tapping the tip of the plug for a moment on the sleeve of the “jack” to ascertain if the line is “busy.” If no click sounds in her ear she--]

[Illustration: Pushes in the plug and with her other hand operates a key on the desk. The first action connects the line of the subscriber called; the second rings his bell. When either party hangs up his receiver, a light glows on the switchboard desk, showing the operator that the conversation is ended.]

A MULTIPLE SWITCHBOARD]

[Illustration: THE BACK OF A MULTIPLE SWITCHBOARD]

[Illustration: THE BIRTHPLACE OF THE TELEPHONE, 109 COURT STREET, BOSTON

On the top floor of this building, in 1875, Prof. Bell carried on his experiments and first succeeded in transmitting speech by electricity]

How the Telephone Came to Be.

It is hard to realize that there was once a time, not so very many years ago, when the telephone was regarded as a scientific toy and hardly anyone could be found willing to invest any money in the development of the telephone business.

[Illustration: ALEXANDER GRAHAM BELL IN 1876]

[Illustration: THOMAS A. WATSON IN 1874]

The story of Professor Alexander Graham Bell’s wonderful invention is full of romantic interest and the early days of its exploitation were replete with dramatic incidents.

~THE MEN WHO MADE THE TELEPHONE~

Young Bell had come to America in 1870 in search of health, the family settling at Brantford, Canada. He numbered among his forebears many distinguished professional men. For three generations the Bells had taught the laws of speech in the universities of Edinburgh, Dublin and London. He himself was an accomplished elocutionist and an expert in vocal physiology.

During the year spent in Canada in regaining his health, Bell taught his father’s method of visible speech to a tribe of Mohawk Indians and began to think about the “harmonic telegraph.”

In 1871 young Alexander Bell accepted an offer from the Boston Board of Education to teach the “visible speech” method in a school for deaf mutes in that city.

For two years he devoted himself to the work with great success. He was appointed a professor in the Boston University and opened a school of “Vocal Physiology” which was at once successful.

He might have continued his career as a teacher had it not been that his active brain still clung to the “harmonic telegraph” idea and his inventive genius demanded an outlet.

[Illustration: PROF. BELL’S VIBRATING REED]

So we find him in 1874 working out his idea of the “harmonic telegraph,” the perfection of which meant a fortune to the young inventor. That he never realized his goal was due to the fact that while experimenting, he made a discovery which led to a far greater invention and one that was fraught with more benefit to mankind than the “harmonic telegraph” could ever have been.

It was while working with his faithful man Friday, Thomas A. Watson, in the dingy little workrooms on Court Street, Boston, that Bell got the inspiration which made him turn from the “harmonic telegraph” to devote himself to the invention which was destined to make his name famous--the speaking telephone.

~THE FIRST SOUND OVER A WIRE~

Mr. Watson has dramatically described the incident as follows:

“On the afternoon of June 2, 1875, we were hard at work on the same old job, testing some modification of the instruments. Things were badly out of tune that afternoon in that hot garret, not only the instruments, but, I fancy, my enthusiasm and my temper, though Bell was as energetic as ever. I had charge of the transmitters, as usual, setting them squealing one after the other, while Bell was retuning the receiver springs one by one, pressing them against his ear as I have described. One of the transmitter springs I was attending to stopped vibrating and I plucked it to start it again. It didn’t start and I kept on plucking it, when suddenly I heard a shout from Bell in the next room, and then out he came with a rush, demanding, ‘What did you do then? Don’t change anything. Let me see!’ I showed him. It was very simple. The make-and-break points of the transmitter spring I was trying to start had become welded together, so that when I snapped the spring the circuit had remained unbroken while that strip of magnetized steel by its vibration over the pole of its magnet, was generating that marvelous conception of Bell’s--a current of electricity that varied in intensity precisely as the air was varying in density within hearing distance of that spring. That undulatory current had passed through the connecting wire to the distant receiver which, fortunately, was a mechanism that could transform that current back into an extremely faint echo of the sound of the vibrating spring that had generated it, but what was still more fortunate, the right man had that mechanism at his ear during that fleeting moment, and instantly recognized the transcendent importance of that faint sound thus electrically transmitted. The shout I heard and his excited rush into my room were the result of that recognition. The speaking telephone was born at that moment. Bell knew perfectly well that the mechanism that could transmit all the complex vibrations of one sound could do the same for any sound, even that of speech. That experiment showed him that the complex apparatus he had thought would be needed to accomplish that long-dreamed result was not at all necessary, for here was an extremely simple mechanism operating in a perfectly obvious way, that could do it perfectly. All the experimenting that followed that discovery, up to the time the telephone was put into practical use, was largely a matter of working out the details. We spent a few hours verifying the discovery, repeating it with all the differently tuned springs we had, and before we parted that night Bell gave me directions for making the first electric speaking telephone. I was to mount a small drumhead of gold-beater’s skin over one of the receivers, join the center of the drumhead to the free end of the receiving spring and arrange a mouthpiece over the drumhead to talk into. His idea was to force the steel spring to follow the vocal vibrations and generate a current of electricity that would vary in intensity as the air varies in density during the utterance of speech sounds. I followed these directions and had the instrument ready for its trial the very next day. I rushed it, for Bell’s excitement and enthusiasm over the discovery had aroused mine again, which had been sadly dampened during those last few weeks by the meagre results of the harmonic experiments. I made every part of that first telephone myself, but I didn’t realize while I was working on it what a tremendously important piece of work I was doing.

[Illustration: WHAT THE FIRST TELEPHONE LOOKED LIKE

ALEXANDER GRAHAM BELL’S FIRST TELEPHONE]

The First Telephone Line.

“The two rooms in the attic were too near together for the test, as our voices would be heard through the air, so I ran a wire especially for the trial from one of the rooms in the attic down two flights to the third floor where Williams’ main shop was, ending it near my work bench at the back of the building. That was the first telephone line. You can well imagine that both our hearts were beating above the normal rate while we were getting ready for the trial of the new instrument that evening. I got more satisfaction from the experiment than Mr. Bell did, for shout my best I could not make him hear me, but I could hear his voice and almost catch the words. I rushed upstairs and told him what I had heard. It was enough to show him that he was on the right track, and before he left that night he gave me directions for several improvements in the telephones I was to have ready for the next trial.”

Then followed many heart-breaking months of experimenting and it was not until the following March that the telephone was able to transmit a complete, intelligible sentence.

[Illustration: TELEPHONE APPARATUS PATENTED IN 1876 BY PROF. BELL, PHOTOGRAPHED FROM THE ORIGINAL INSTRUMENTS IN THE PATENT OFFICE AT WASHINGTON]

On February 14, 1876, Professor Bell filed at Washington his application for patents covering the telephone which he described as “an improvement in telegraphy” and on March 3, of the same year, the patent was allowed.

That was the year of the Centennial Exposition at Philadelphia and Professor Bell had a working model of the telephone on exhibition. Tucked away in an obscure corner it had attracted but little attention, until on June 25th an incident occurred which had a tremendous effect in giving to the new invention just the sort of publicity it needed.

Professor Bell himself describes the incident in the following interesting manner:

“Mr. Hubbard and Mr. Saunders, who were financially interested in the telephone, wanted this instrument to be exhibited at the Centennial Exhibition. In those days--and I must say even up to the present time I am afraid to say it is true--I was not very much alive to commercial matters, not being a business man myself. I had a school for vocal physiology in Boston. I was right in the midst of examinations.

“I went down to Philadelphia, growling all the time at this interruption to my professional work, and I appeared in Philadelphia on Sunday, the 25th. I was an unknown man and looked around upon the celebrities who were judges there, and trotted around after the judges at the exhibition while they examined this exhibit and that exhibit. My exhibit came last. Before they got to that it was announced that the judges were too tired to make any further examinations that day and that the exhibit could be examined another day. That meant that the telephone would not be seen, for I was not going to come back another day. I was going right back to Boston.

~HOW AN EMPEROR SAVED THE TELEPHONE~

“And that was the way the matter stood--when suddenly there was one man among the judges who happened to remember me by sight. That was no less a person than His Majesty Dom Pedro, the Emperor of Brazil. I had shown him what we had been doing in teaching speech to the deaf in Boston, had taken him around to the City School for the Deaf and shown him the means of teaching speech, and when he saw me there he remembered me and came over and shook hands and said: ‘Mr. Bell, how are the deaf mutes of Boston?’ I said they were very well and told him that the next exhibit on the program was my exhibit. ‘Come along,’ he said, and he took my arm and walked off with me--and, of course, where an Emperor led the way the other judges followed. And the telephone exhibit was saved.

[Illustration: THE FIRST TELEPHONE SWITCHBOARD USED. EIGHT SUBSCRIBERS.]

An Emperor Wonders.

“Well, I cannot tell very much about that exhibit, although it was the pivotal point on which the whole telephone turned in those days. If I had not had that exhibition there it is very doubtful what the condition of the telephone would be today. But the Emperor of Brazil was the first one to bring that situation about at that time. I went off to my transmitting instrument in another part of the building, and a little iron box receiver was placed at the ear of the Emperor. I told him to hold it to his ear, and then I heard afterward what happened. I was not present at that end of the line. I went to the other end and was reciting, ‘To be or not to be, that is the question,’ and so on, keeping up a continuous talk.”

“I heard afterward from my friend, Mr. William Hubbard, that the Emperor held it up in a very indifferent way to his ear, and then suddenly started and said, ‘My God! it speaks!’ And he put it down; and then Sir William Thomson took it up and one after another in the crowd took it up and listened. I was in another part of the building shouting away to the membrane telephone that was the transmitter. Suddenly I heard a noise of people stamping along very heavily, approaching, and there was Dom Pedro, rushing along at a very un-Emperor-like gait, followed by Sir William Thomson and a number of others, to see what I was doing at the other end. They were very much interested. But I had to go back to Boston and couldn’t wait any longer. I went that very night.”

“Now, it so happened there, that, although the judges had heard speech emitted by the steel disc armature of this receiving instrument, they were not quite convinced that it was electrically produced. Some one had whispered a suspicion that it was simply

the case of the thread telegraph, the lovers' telegraph, as it was known in those days, and that the sound had been mechanically transmitted along the line from one instrument to the other. Of course, I did not know about it at that time; but when the judges asked permission to remove the apparatus from that location I said, 'Certainly, do anything you like with it.' But I could not remain to look after it; they had to look after it themselves."

"My friend, Mr. William Hubbard, who had kindly come up from Boston to help me on this celebrated Sunday, June 25, said he would do his best to help them out, although he was not an electrician. He knew nothing whatever about the apparatus, beyond being in my laboratory occasionally, knowing me well. But he undertook to remove this apparatus and set up the line under the direction of the judges themselves. So they had an opportunity finally of satisfying themselves that speech had really been electrically reproduced."

"Sir William Thomson's announcement was made to the world in England, before the British Association, and the world believed--and from that time dates the popular interest in the telephone."

In October, 1876, the first outdoor demonstration, in which conversation was carried on over a private telegraph wire, borrowed for the occasion, took place between Boston and Cambridge, a distance of two miles.

In April, 1877, the first telephone line was installed between Boston and Somerville.

A month later an enterprising Boston man put up a crude switchboard in his office and connected up five banks, using the system for telephoning in the day-time and as a protection against burglars at night. This was the beginning of the exchange system, all previous telephoning having been between two parties on the same circuit.

~NINE MILLION TELEPHONES IN U. S.~

Soon after exchanges sprang up in several cities, and by August of that year there were 778 Bell telephones in use. From this modest beginning the telephone has grown until on January 1, 1914, there were 13,500,000 telephones in the world, nearly 9,000,000, or over 64 per cent being in the United States.

[Illustration: MODERN DISTRIBUTING FRAME

When the wires come to this frame they are in numbered order in the cable. The main frame redistributes these wires so that they are arranged according to their call numbers, making it possible to connect any wire with any other wire anywhere that telephone service is installed.]

[Illustration: HOW THE WIRES ARE PUT UNDERGROUND

Breaking Up the Asphalt Pavement. First Step in Laying an Underground Cable.]

[Illustration: Laying Multiple Duct Tile Subway Through Which the Cables Will Run.]

[Illustration: Feeding Cable Into Duct as It is Being Pulled Through Subway from the Other End.]

[Illustration: A CABLE TROUBLE]

The use of the telephone instrument is common, but it affords no idea of the magnitude of the mechanical equipment by which it is made effective.

~UNSEEN FORCES BEHIND YOUR TELEPHONE~

To give you some conception of the great number of persons and the enormous quantity of materials required to maintain an always-efficient service, various comparisons are here presented.

[Illustration: TELEPHONES. Enough to string around Lake Erie--8,000,000, which, with equipment, cost at the factory $45,000,000.]

[Illustration: WIRE. Enough to coil around the earth 621 times--15,460,000 miles of it, worth about $100,000,000, including 260,000 tons of copper, worth $88,000,000.]

[Illustration: LEAD AND TIN. Enough to load 6,600 coal cars--being 659,960,000 pounds, worth more than $37,000,000.]

[Illustration: CONDUITS. Enough to go five times through the earth from pole to pole--225,778,000 feet, worth in the warehouse $9,000,000.]

[Illustration: POLES. Enough to build a stockade around California--12,480,000 of them, worth in the lumber yard about $40,000,000.]

[Illustration: SWITCHBOARDS. In a line would extend thirty-six miles--55,000 of them, which cost, unassembled, $90,000,000.]

[Illustration: BUILDINGS. Sufficient to house a city of 150,000--more than a thousand buildings, which, unfurnished, and without land, cost $44,000,000.]

[Illustration: PEOPLE. Equal in numbers to the entire population of Wyoming--150,000 employes, not including those of connecting companies.]

The poles are set all over this country, and strung with wires and cables; the conduits are buried under the great cities; the telephones are installed in separate homes and offices; the switchboards housed, connected and supplemented with other machinery, and the whole system kept in running order so that each subscriber may talk at any time, anywhere.

Where Does Sound Come From?

Somebody or something causes every sound we hear. Sounds are the result of disturbances in the air. Sound is produced by waves in the air. The buzz of the bumble-bee is caused by the quick movement of his wings in the air. The wings themselves do not make the sound, but their motion causes waves or vibrations in the air which produce the sound of buzzing. Every motion made by anybody or anything produces waves in the air just like the waves you see in the water--a big movement makes a big wave and a tiny movement a tiny wave. When you clap your hands you make a disturbance in the air which causes a sound--the harder you clap the louder the sound. You can hear this sound and anybody else near can hear it. If there were no air about us, however, we would hear no sound, even if we could live in such a condition of things, for it is the air waves produced striking against the drum of our ears that enable us to discern sounds. When we talk we make air waves also and thus produce sound. If you were deaf, and talked, you could not hear any sound, because even when there are air waves they must still strike against a sounding board in order to be recognized as sound--and the drum of our ear is our sounding board for hearing sounds.

When the air waves produced are regular we call the sound musical, and when they are irregular we call it noise. Some people can make musical sounds when they sing, while others cannot.

If you take a piece of thin wire and stretch it tightly, fastening it at both ends, and then pull it with your finger and let go, you will hear a musical sound, because the vibrations produced will be regular and will continue for some time. If you shorten the distance on the wire where it is fastened at both ends and pull it as before, the sound produced will be in a higher key. If you take a guitar and snap the big G string you will produce the bass note of G. If the other G string (the smaller one) is in tune (if you watch the smaller one closely while you strike the larger one) you will notice the smaller one vibrate also. Sound waves of the same tone, although in different octaves, produce the same sounds, although in different keys.

This is the principle on which the piano is made to produce music. Inside the piano are wires of different lengths and the keys of the piano are arranged to operate certain little hammers, each of which strikes a certain wire. Every time you strike a piano key you cause one of the little hammers to hit its wire--the wire then makes vibrations which cause air waves. The air waves strike against the sounding board which is located behind the wires, and being thrown back into the air, strike against the drum of our ears, and we can hear the note.

Why Can We Make Sounds With Our Throats?

The sounds we make when we talk are produced in exactly the same way with the exception of the little hammers. In our throats are two cords which we call our vocal cords. When we talk we cause these cords to vibrate and thus we make the sounds of our voices. The most wonderful part of this voice of ours is that with only two vocal cords or wires, we can produce practically all the notes that can be made with a piano, which has a wire or cord for every note, excepting that we cannot make so many at one time. The human throat is so wonderfully constructed that we can lengthen or shorten our vocal cords at will and produce, with two strings, in our throats as many notes as it takes the piano many more strings to produce.

Why Does the Sound Stop When We Touch a Gong that Has Been Sounded?

When we touch the gong we stop the sound waves which the gong gives off when it is struck. These sound waves continue after the gong has been struck in continuous vibrations until something stops them. When you touch the vibrating gong, you stop its vibrating. If you only touch your finger to the vibrating gong you can feel the vibrations which cause a little tickling sensation. Naturally when you stop these vibrations you stop the air waves which the vibrations cause, and thus also the sound of these air waves striking your ear are stopped and the sound ceases.

How Can Sound Come Through a Thick Wall?

A sound will come through a thick or thin wall only if the wall is a good conductor of sound. Some things are good conductors of sound and others are not, just as some things are good conductors of electricity and others are not. If a wall is built of materials all of which are good conductors of sound, the sound will come through it no matter how thick. Wood is an especially good conductor of sound. It is even better than air. You can stand at one end of a long log and have another person at the other end hold up his watch in the air, and you cannot hear the watch tick, but if the watch is “going” as we say, and you ask the person holding it to put the watch against his end of the log, and you then put your ear to the other end, you can hear the watch ticking almost as well as if you had it to your own ear. In like manner you can hear the scratching of a pin at the other end of the log. When you put your ear against a telegraph pole you can hear the hum of the wires while you cannot hear it through the air. All sound is produced by sound waves and many solids are better conductors of sound waves than the air.

Sound waves, however, will sometimes not be heard as plainly through a wall, because of the fact that the wall may be made of materials which are not equally good conductors of sound. When a sound wave strikes a poor conductor it loses some of its power and the sound, although it may be heard through the wall, will be fainter.

What Is Meant by Deadening a Floor or a Wall?

By deadening a floor, for instance, we mean inserting between the ceiling of the room below and the floor above, or in the instance of a deadened wall, between the two sides of the wall, some substance like felt, paper or other non-conductor of sound, which will prevent the sound waves from passing through. This deadens them to the passing of sound or makes them sound-proof.

What Makes the Sounds Like Waves in a Sea Shell?

The sounds we hear when we hold a sea shell to the ear are not really the sound of the sea waves. We have come to imagine that they are because they sound like the waves of the sea, and knowledge that the shell originally came from the sea helps us to this conclusion very easily.

What Are the Sounds We Hear in a Shell?

The sounds we hear in the sea shell are really air waves or sounds made by air waves, because all sounds are produced by air waves.

The reason you can hear these sounds in a sea shell is because the shell is so constructed that it forms a natural sounding box. The wooden part of a guitar, zither or violin is a sounding box. They have the faculty of picking up sounds and making them stronger. We call them “resonators,” because they make sounds resound. The construction of a sea shell makes an almost perfect resonator. A perfect resonator will pick up sounds which the human ear cannot hear at all and magnify them so that if you hold a resonator to the ear you can hear sounds you could not otherwise hear. Ear trumpets for the deaf are built upon this principle.

Sometimes when you, with your ear alone, think something is absolutely quiet, you can pick up a sea shell and hear sounds in it. But the sea shell will magnify any sound that reaches it.

It would be possible, of course, to take a sea shell to a place where it would be absolutely quiet and then there would be no sounds.

There are such places, but very few of them. A room can be built which is absolutely sound proof.

The Story in a Suit of Clothes

Where Does Wool Come From?

We could not write the story of a suit of clothes without dealing largely with the sheep, for it is only from the wool of the sheep that the best, warmest and most lasting garment can be made. In order that we may properly understand the development of the great wool and clothing industry in America we must supply a brief history of our sheep industry, for the sheep must always come before the clothing.

Who Brought the First Sheep to America?

The sheep is not a native of America, but it came here with the first white men. History records that Columbus on his way to this country stopped at the Canary Islands to take on stores. Among other things he loaded a number of sheep, some of which were later landed on the new continent. What became of this early importation history does not record, but it is probable that most, if not all, of them perished from the attack of wild animals or at the hands of the natives. However, when settlers began pouring into the new world many of them brought along their sheep, so that from the earliest colonial days the sheep constituted our most numerous domestic animals. This, indeed, was necessary, for if the colonist was to survive the rigor of our climate he must have an abundant supply of woolen clothing. In those days clothing materials were limited to wool, flax and the skins of animals, and, as may be supposed, wools were in very great demand. England and most European countries prohibited the exportation of wool, in order to increase the demand for the clothing which she manufactured. However, as our new colonist had ample time and but little money, he desired to make his own clothing rather than send such funds as he had to the mother country. Therefore, the new settler, as a matter of necessity, was forced to increase the domestic supply of wools.

Who Started to Make Clothing from Wool in America?

Early records reveal that shortly after the year 1600 many of the colonies passed laws for the purpose of encouraging the sheep industry. In fact, some of them went so far as to prohibit the transportation of sheep or wool from one colony to another. However, our new sheep industry prospered, and well it should, for it had the backing of every prominent patriot of the early days. Washington, Jefferson, Madison, and Franklin all were enthusiastic advocates of sheep husbandry, for they knew that unless a people had a large domestic supply of wool they could not long remain independent or hope to gain independence from foreign countries. In fact, at one time Washington owned as many as one thousand sheep, and if he lived in the present day he would be regarded as a sheep baron. Wool, next to food, is the most vital necessity of a people, for when wars come wool becomes a contraband, and all foreign supplies are shut off. Thus, in stimulating a domestic wool supply the great wisdom of our early patriots was vindicated with the coming of the Revolutionary War. When that great struggle came our foreign wool supply was shut off, but on account of the foresight of these patriots in encouraging home production, our colonists had a supply ample for most of their needs.

We not only had the wool, but the housewife had learned the art of manufacturing wool into clothing by means of the spinning wheel, so that when our soldiers went forth in that great struggle, which was to bring to us independence, they were clad in garments made of American grown wool and manufactured by the good housewife during her hours of leisure.

When affairs became tranquil, following the close of the Revolution, settlement, which had largely been confined to the Atlantic coast, pushed westward farther and farther into the wilderness. Each of these settlers took with him his supply of sheep, for the purpose of furnishing wool for clothing and meat for food. In the early days wool was not grown for the purpose of sale, but to be used entirely by the family of the producer. However, when settlement reached the Mississippi River, conditions changed. Wool manufacturing had then been established in the land, and it became customary to raise wool to sell to these manufacturers, who had located along the Atlantic seaboard.

Why Does the Sheep Precede the Plow in Civilizing a Country?

In all countries the sheep has been the pioneer of civilization. They have settled and developed practically all new lands. In fact, so firmly established has been this rule that it seems almost necessary that the sheep should precede the plow, and thus prepare land for agriculture. The reason for this is that the sheep is a tractable animal and depends on man to guide its every step. It can endure hardships that would destroy other forms of animal life. However, the maintenance of a sheep industry requires an abundance of

labor, and in this way settlement always follows the sheep. So has it been in foreign countries, and so was it in this country.

Where Does Most of Our Wool Come From?

Sheep came into our western states early in the seventies, at a time when these states were thinly settled, but following the sheep came the labor incident to its care, and thus the railroads, stores, cities and schoolhouses found their way into the land. Originally all of our sheep industry was east of the Mississippi River. Then for a time it was east of the Missouri River. To-day west of the Missouri River we have about 23,000,000 aged sheep, or more than one-half of the total in the United States. In the pioneer days the western sheep skirmished on the range for most of the food that it obtained. To-day conditions are different, and, while the sheep is on the range for a short time each year, it spends its summer in the National Forest, for which grazing a fee is paid to the Federal Government. Its winters are spent largely around the hay-stack of the farmer, and about fifty to sixty cents' worth of hay is fed to each sheep in the West each winter. With the coming of spring the western sheep are divided into bands of about 1500, and each two bands are placed in care of three caretakers, who care for and protect the sheep either on the deeded land of the owner or on the land rented from the Federal Government.

[Illustration: SHEEP COMING OUT OF FOREST]

How Much Wool Does America Produce Yearly?

So much for the history of our sheep. A few words now about wool. The total wool crop of the United States is approximately 300,000,000 pounds per year. The value of this crop is around $60,000,000 annually.

How Do We Get the Wool Off the Sheep?

With the coming of spring our sheep are driven to large central plants, where they are shorn by the use of machines driven by electricity or steam power. One man shears about one hundred and fifty sheep per day. For this he receives eight cents per head. When the wool is taken off the sheep it is gathered up and carefully tied with string made of paper. The tied fleece is then dropped into an elevator, and is carried up about ten feet, where it is dropped into a large sack about three feet in diameter and seven feet long. In this sack there is always a wool tramper, who keeps tramping the fleeces down, so that about forty fleeces are finally put into each sack, making the weight of the sack approximately three hundred pounds. As these sacks are filled they are carefully stored in a dry shed, and, when shearing is completed, are hauled to the railroad station and shipped to the great wool centers of Boston or Philadelphia. While the bulk of the wool in the United States is produced west of the Missouri River, that territory manufactures very little wool. So the western sheepman, who is thus forced to grow his wool in the western states, pays about two cents a pound freight on it back to the eastern market, where it is sold and later manufactured into cloth. A part of this same clothing is then shipped west, to be sold to the very man, in some instances, who produced the wool out of which it is made.

American wool, taken as a whole, is the best wool grown in the world. It is not as soft as some Australian wool, but all of it possesses a greater strength than foreign wools, and it has long since been determined that clothing made of American wool will give better service than that made of foreign wool. Of the wool used in the United States for the manufacturing of clothing we produce about 70 per cent and import about 30 per cent.

How Much Does the Wool In a Suit of Clothes Cost?

It is customary for the person who buys clothing made of wool to believe that the value of the wool in the cloth is what makes the clothing seem expensive. However, if we take a man's suit made of medium-weight cloth, such as is worn in November, we find that it requires about nine pounds of average wool to make the suit. For this wool the sheepman receives an average of seventeen cents per pound, so that out of the entire suit the man who produces the material out of which the suit is made receives a total of $1.53. A suit such as is here described would be of all wool and free from shoddy or any wool substitute. It would be a suit that would be sold by the storekeeper at $25.00, and if you had it made by the tailor he would charge you $35.00. Yet the wool-grower furnished all the material out of which the suit was made, and received as his share but $1.53. Thus it will be clear to the person who buys clothing and reads these lines that no longer can the blame for the high cost of clothing be laid at the door of the wool-grower.

While the wool-using population of the world is increasing very rapidly, the number of wool-producing sheep in the world is decreasing. Ordinarily this would mean that a point would be reached where the supply of wool would be totally inadequate to meet

the needs of the public. However, this unfortunate possibility is being averted by the energy and thrift of the sheepmen in breeding sheep that produce more and better wool than was the case in the past. The sheep which Columbus brought to this country, and, in fact, all the sheep of the world in that day, produced wool of very coarse, inferior quality, and but very little of it. One hundred years ago our sheep did not average three pounds of wool per head, but by careful breeding and better feeding we have brought the average fleece up to slightly more than seven pounds. Of course, some sheep produce decidedly more wool than this, but the fact that in one hundred years we have more than doubled the amount of wool that a sheep produces and increased its quality very materially speaks well for the ingenuity and determination of our sheep producers. Probably as time goes on the average fleece may be still further increased, so that in the next twenty-five years it is not too much to hope that our sheep will produce on an average of one pound more wool than they now do.

Of course, as wool comes from the sheep, it naturally contains much dirt. The sheep have run on the range or in the open pasture during much of the year, and dust and dirt has settled into the wool. Then, besides producing wool, the sheep excrete into the wool a fatty substance known as wool fat. When the fleece is taken from the sheep and sent to the market the first thing that the manufacturer does with the fleece is to wash out all this foreign matter. The foreign matter is of a considerable quantity, for 60 per cent of wool as it comes from the sheep is dirt and grease, so that only 40 per cent of the sheep's fleece represents wool fibres.

This wool fibre is a very delicate affair, being made up of thousands of little cells, one laid on top of the other. On the surface of the fibre are a lot of scales arranged something like the scales on a fish. In the process of manufacturing the scales on one fibre lock with scales on another fibre, and in that way the fibres are held together in the piece of cloth.

When wool is received at the factory it is in fleeces, and each fleece contains different kinds of fibres--long and short--coarse and fine, and it is necessary that these should be sorted into different kinds or grades, as may be desired--perhaps six or eight different kinds, according to the particular uses to which the different qualities are to be put.

[Illustration:

Copyright American Woolen Company

WOOL SORTING]

The fleece is spread out on a table, the center of which is covered with wire netting, and through this netting part of the dust and other matter from the wool falls while the sorting is going on. Sorters tear with the hands the different parts of the fleece from each other and separate them into piles, according to their different qualities.

All unwashed wool contains a fatty or greasy matter called yolk, which is a secretion from the skin of the sheep. The effect of this yolk is to prevent the fibres of the wool from matting, except at the ends, where, of course, it collects dust, and, forming a sort of a coating, really serves as a protection to the rest of the fleece while on the sheep's back.

After the wool is sorted it is next cleansed or scoured, in order to remove all this yolk, dirt and foreign matter, and this is accomplished by passing the wool, by means of automatic rakes, through a washing machine, consisting of a set of three or four vats or bowls, which contain a cleansing solution of warm, soapy water, until all the grease and dirt have been removed.

Each bowl has its set of rollers, which squeezes out the water from the wool before it passes into the next bowl. Having passed through the last bowl and set of rollers the wool is carried on an apron made of slats on chains, to the drying chamber, called the dryer, where is taken out most of the moisture.

The wool is now blown through pipes or carried on trucks to the carding room.

~DIFFERENCE IN WOOLENS AND WORSTEDS~

From this point the wool follows one of two different processes of manufacture--that of making into worsteds or that of making into woolens.

Speaking in a general way, worsted fabrics are made of yarns in which the fibres all lie parallel, and woolens are made of yarns in which the fibres cross or are mixed. Ordinarily, worsteds are made from long staple wools, and woolens from short staple wools.

[Illustration:

Copyright American Woolen Company

WOOL SCOURING]

By means of the comb the fibre is still further straightened out, the short stock and noil, or nibs, are removed, and when the sliver comes from the combs most of the fibres are parallel to each other. A number of the slivers taken from the comb are then put through two further operations of gilling, and wound into a large ball, which is called a finished top.

The next process in the manufacture of worsteds is carding. In this process the wool is passed between cylinders and rollers, from which project the ends of many small wires. These cylinders revolve in opposite directions. The result is the opening, separating and straightening of the fibres; and the wool is delivered in soft strands, which are taken off by the doffer comb and wound upon a wooden roll into the shape of a large ball, known as a card-ball or card-sliver, or put into a revolving can. The sliver from a number of these balls or cans is now taken and put through what is known as the gilling machine, which to a degree straightens the fibres.

From the gilling machine the wool comes off in soft strands. Four strands are then taken to the balling machine, where is made a large ball, ready for the combing. It takes eighteen of these balls to make a set or fill up the comb.

The dyeing is done in three ways--in the top, in the thread or skein after being spun, or in the piece after it is woven. If the wool is to be stock dyed--that is, dyed in the top--it is sent to the dyehouse to be dyed the shade required, and afterwards returned to be gilled and recombed ready for the drawing.

[Illustration:

Copyright American Woolen Company

WORSTED CARDING]

Up to this point there has been no twist given to the wool, nor any appearance of a thread. The top, the soft untwisted end, is now run through the drawing machine, the process sometimes consisting of nine distinct operations, and is drawn and redrawn until reduced to the size required for its special purpose; and the stock is then delivered to the spinning room on spools, and is called roving.

[Illustration:

Copyright American Woolen Company

GILLING AFTER CARDING]

[Illustration:

Copyright American Woolen Company

COMBING]

In the spinning the process of drawing continues until the twisted thread is reduced to the size required, which, either singly or twisted together in two, three or four strands, is to be used for weaving.

The yarn is then very carefully inspected, and all imperfections which would show in the finished goods are removed, and, if it is to be dyed in the skein, the yarn is taken to a reel, where the skeins are made ready for the dyehouse.

~HOW CLOTH IS MADE FROM WOOL~

The threads must now be prepared for the loom, in order that the actual weaving may be done. The thread is used in two ways in weaving--as warp, which is the thread which runs lengthwise of the cloth, and as filling, or woof, which runs across the cloth from side to side.

[Illustration:

Copyright American Woolen Company

GILLING AND MAKING TOP AFTER COMBING]

The warp threads--the threads which run lengthwise of the cloth--are sized and wound upon large reels, and from these transferred to a large wooden roll called the warp beam, which holds all the warp threads, usually several thousands.

The filling threads are put on shuttle bobbins and placed in the shuttles to be refilled by the operatives as required, and as the weaving progresses.

The warp beam is then taken to the drawing-in room, where these several thousand threads are drawn through wire heddles in a frame called the harness, then drawn through a wire reed. The completed warp beam is now ready for the loom.

The harnesses are placed in the loom, and by means of what is called the “head-motion,” part of the threads are raised and part are lowered. This allows the filling shuttles to pass above some threads and below others, filling out the pattern required.

The cloth, having been made in such length as is desired, is taken from the loom, and, by what is known as burling and mending, any knots or threads woven in wrongly are removed, and any imperfections which have been discovered through a careful examination are corrected.

The web or cloth is scoured or washed and the oil and any foreign matter removed.

Undressed fabrics would now be fulled. This consists of running cloth through a fulling machine, where, moistened with a specially prepared soap, it is subjected to a great pressure and pounding, which aids in giving the required finish.

There are different kinds of finishes which require different treatments, and it would be impracticable for us to dwell in detail upon this matter here.

If dyed in the piece, the web or cloth is taken to the dyehouse and dyed. It is thoroughly rinsed, all moisture is extracted from it, and it is dried.

After drying the cloth is run through a machine by which it is brushed and sheared, the brushing lifting the long fibres, and the shearing cutting them off at even length. The cloth is put through the press, which irons it out, giving it the lustre or the finish that is desired. It is examined again for further imperfections, and if such have occurred they are corrected.

Measuring, weighing, rolling and tagging follow, and the cloth is packed and ready for the market.

Woolens are made from short staple wools, known as clothing wools, and in the finished woolens the fibres of the yarns cross or are mingled together. In the case of woolens, after the scouring, it is frequently necessary to remove burrs or other vegetable matter from the wool. To accomplish this the wool is dipped in a bath of chloride of aluminum or sulphuric acid solution, then the moisture is extracted and the wool is put through a drier, where the temperature must be at least 212 degrees. This heat carbonizes the foreign substance, but has little effect on the animal fibres of the wool.

[Illustration: FINISHING BOX

Next, an ingenious machine called the burr picker removes the burr.

Sometimes there is to be a blend of the wool with other stocks, and in that case the several different wools are mixed together.

~HOW WOOLEN CLOTH IS DYED~

Dyeing of woolens is done in three ways--in the wool, in the thread after it is spun, or in the piece after it is woven. If the wool is to be “dyed in the wool” it is now conveyed to the dyehouse, dyed the shade required, then returned to the mixing room.

During the process of scouring, when the yolk was removed, a large part of the natural oil of the wool was also eliminated, and, in order to restore this lubricant, the wool is sprinkled with an oil emulsion, and the mixing picker thoroughly blends the wools.

From here the wool goes to the cardroom, and by means of the carding machine the fibres are carded and drawn and delivered to the finisher in a broad, flat sheet. By means of the condenser it is divided into narrow bands, and the wool--free as yet from twist--comes out in soft strands. These strands or threads are called roping.

WEAVING AND SCOURING]

Now comes the mule spinning. The roping passes through rolls by which it is drawn and twisted to the size required, and wound on paper cop tubes or bobbins. Such of the yarn as is to be used for warp is then spooled from the bobbins to dresser spools. It is sized and wound upon large reels: from these transferred to the warp beam, as in the case of worsteds.

The processes of drawing-in, preparation for weaving, burling and mending are practically the same as in the case of worsteds.

~HOW THE CLOTH IS MADE PERFECT~

The finishing processes of woolens, like the finishing processes of worsteds, vary with different fabrics, some fabrics being scoured and cleansed in the washers before fulling, others going to the fulling mill without cleansing. After fulling, the cloth is again washed and rinsed, and if necessary to remove any vegetable fibres it is carbonized.

Napping or gigging raises the fibres to the nap desired. Gigging is done by means of a wire napping machine or teasel gig, which raises the ends of the fibres on the face of the cloth. The teasel is a vegetable product about the shape of a pine cone, and it is interesting to note that no mechanical contrivance has ever been invented to equal it for the purpose.

[Illustration: SPINNING THE WOOL

ENGLISH CAP SPINNING]

The napping which has been raised by the teasel is sheared or cut to a proper length by machine. The cloth is pressed, and, if it is desired to finish it with lustre, it is wound upon copper cylinders and steam is forced through it at a high pressure.

FINISHER WOOLEN CARDING]

Next the cloth is dyed, if it is to be piece-dyed--that is, dyed in the piece. If the cloth is a mixture, the wool was dyed immediately after the scouring. In worsteds the dyeing is done either just after it has been subjected to the first combing processes, or the yarn is dyed in the skein or hank.

FINISHED CLOTH, READY FOR THE TAILOR]

In the dry finishing the cloth is finished with various kinds of finishes desired, and it is steamed, brushed, sheared and pressed. Another examination for any imperfections or defects follows; the cloth is measured, packed and tagged and is ready for the market.

The difference between worsteds and woolens is principally that in the threads or yarns from which worsteds are made the fibres of the wool lie parallel, one to another, being made from combed wool, from which the short fibres have been removed; and woolens are made from yarns in which the fibres cross and are matted and intermixed. When finished the effect of worsteds and woolens is materially different. Upon examination it will be found that the worsted thread resembles a wire in evenness, while the woolen thread is uneven and irregular.

A worsted fabric when finished has a clear, bright, well defined pattern, seems close and firmly woven, and is of a pronounced dressy effect; while woolen cloths are softer, they are more elastic, the colors are more blended, the threads are not so easily distinguishable and the general effect is duller.

Why Can’t We See in the Dark?

We cannot see in the dark because there is no light to see by. To understand this we must first understand that when we see a thing, as we generally say, we do not actually see the thing itself, but only the light coming from it. But we have become so used to saying that we see the thing itself that for all practical purposes we can accept that as true, although it is not scientifically exact. Scientifically speaking, we see that part of the sunlight or other light which is shining upon it, which the object is able to reflect.

If there were no air about us we could not hear any sounds, no matter how much disturbance people or things created, because it requires air to cause the sound waves which produce sound, and air also to carry the sound waves to our ears. In the same way, if there is no light to produce light rays from any given object to our eyes, we can see nothing. It requires light waves to produce the reflections of objects to our eyes. Without light our eyes and their delicate organs are useless. You cannot see yourself in a mirror when the quicksilver which was once on the back of the glass has been removed, because there is then nothing to reflect the light. We can only see things when there is light enough about to reflect things to our eyes. When it is dark there is no light, and that is the reason we cannot see anything in the dark.

Why Can Cats and Some Other Animals See in the Dark?

They cannot see in the real dark any more than human beings. These animals can find their way in the dark and can see more than a human being, because of one distinct difference in their eyes, which may for them be considered an advantage. The pupils of their eyes can be made much larger, and they can, therefore, let more light into their eyes than people. The result is that when it is so dark that you cannot see a thing and you decide it is really dark, the cat can still see, because there is always a little more light left and she can open the pupils of her eyes and make them larger, thus letting in more light, and the little bit of light there is still left gets into her eyes and she is able to see. But in a really dark room a cat could see no more than you can. You see, our eyes open and shut more or less just like those of the cat, according to the intensity of the light. When you go out of the dark and shaded room into the bright sunlight and look at the sun, you naturally squint your eyes without deliberately intending to do so. This is nature’s way of preventing too much light getting into your eyes at one time. Gradually the pupils of your eyes contract and get smaller, until you can see, without squinting, anything in the sunlight. If, then, you were to go right back into a dark or shaded room, you would have to wait a moment or two before you could see things distinctly in the room--until the pupils of your eyes had dilated (become larger), so as to let in enough light to enable you to see normally. The eye automatically enlarges and contracts the pupil of the eye, to enable us to see distinctly in either light or less light places.

Why Is It Difficult to Walk Straight with My Eyes Closed?

The reason we cannot do this always is because when we walk naturally the steps taken by our right and left feet are not of equal length. This difference in the length of the steps is due to the fact that our legs are never exactly the same length. We think of them generally as of the same length, but they are not, and this will be proven if you measure them accurately. Now, then, the longer of the legs will always take a longer step than the shorter one, and so, if our eyes are shut, we walk in circles, unless we have something to guide us. When we walk with our eyes open, we are able to overcome the tendency to walk in circles, because our eyes help the brain to direct the legs on a straight course. Another reason which affects the matter is that our eyes are very necessary in keeping our bodies balanced on our feet, and it is very difficult to learn to keep the body balanced with the eyes closed. Now, when your eyes are closed and you attempt to walk in a straight line your body balances from one side to the other, and this fact, coupled with the first reason given, makes your course irregular. But, say you, the man on the tight-rope has his eyes bandaged and he walks a very straight line. Yes; but remember that he has a straight tight-rope to guide him, and all he needs is to maintain his balance. One can learn to walk in a straight line with the eyes closed, but it takes a good deal of practice, as you will learn if you try.

Why Can’t We Sleep with Our Eyes Open?

We cannot sleep with our eyes open, because to be asleep involves losing control of most of the functions of the body. When we sleep the brain sleeps also. Perhaps it would be stated more clearly to say that we cannot sleep while the part of the brain which controls our activities is awake. There is a part of the brain which has the power to open our eyes, i. e., lift the eyelids, and when that portion of the brain ceases to exercise its power to keep the eyes open, they go shut. Even when we are awake that part of our brain cannot keep our eyes from winking, because there is another part of the brain which sees to it that our eyes wink every so often. This is done for the purpose of washing the eye-ball, and is the answer to another of your questions which is given in another

place in this book. When the engineer at the electric light plant shuts off the power all the lights go out, and when you go to sleep you automatically shut off the power that opens your eyes, and the eyes are shut. The brain is asleep also, and if it is not completely asleep, you are restless.

Why Do Our Eyes Sparkle When We Are Merry?

If you should watch very closely the eyes of a merry person when you see them sparkle you would probably notice that the eyelids move up and down more often under such conditions than ordinarily, and if you know what moving the eyelids up and down in front of the pupil of the eye does, you will have your answer.

Every time the eyelid comes down it releases a little tear, which spreads over the eyeball and washes it clean and bright. It does this every time the eyelid comes down. Now, there is something about being merry which has the effect of making the eyelids dance up and down, and thus, every time the lid comes down, the ball of the eye is washed clean and bright, and gives it the appearance of sparkling, as we say.

Why Do We Laugh When Glad?

We laugh when glad because the things which make us laugh combine together to rouse those parts of the body which are involved in a good laugh to act in a certain harmony, and when this combination is arranged in a certain way it produces a laugh. Certain things in the world, whether they are funny, ludicrous, or other things that produce the laughing effect, cause the brain to work certain muscles and nerves in a combination that produces a laugh. The impression which reaches the brain causes these muscles and nerves to act involuntarily and the laugh comes. It works just like the keys of the piano. Some combinations of notes produce sad sounds and other combinations produce glad sounds, but the combination when once touched will always produce the same sound. It is the impressions made on the brain which start the proper combination, and it does this instantly. Just as a pin prick in the arm will at once send a “hurt” message to the brain and cause the brain to jerk the arm away, so a laugh-producing combination of sounds, or things we see, or feel, sends an impression to the brain which at once sends out the “laugh” order. Some things make some people laugh while they do not affect others at all. That is because our brains are not always the same in regard to recording impressions. Some things impress some brains one way and others entirely in a different way or not at all. You do not laugh so heartily the second time you hear a funny story, because the impression the brain receives when the story is told the second time is not so vivid.

Why Do I Laugh When Tickled?

Practically the same things happen when we are tickled, and explains why you laugh when tickled. When some one tickles the bottom of your feet or your ribs or another part of your body it produces, in most cases, the same effect on the brain as the laugh-producing sound or sight, and arouses the same combination of muscles and nerves to activity. It is just like pushing the button of an electric bell. When you push the button the contact produces the spark which sets the machinery of the bell in motion and the bell rings and will continue to ring as long as you keep your finger on the button, or until the spark-producing power of the battery is gone. Then, as in the case of the bell, you cease to laugh, because the spark that produced the laugh combination is gone. That is why some things tickle some people very much and do not affect others. Some are not so sensitive to the laugh-producing combination as others. After the thing that tickles you has been going on for some time you are not tickled into laughter any more, because the impression on the brain ceases to be as strong.

Why Don’t I Laugh When I Tickle Myself?

Your mind tells you there is no need to laugh when you tickle yourself. Your mind will not respond to the tickling sensation when it is aware that the cause of the tickle is yourself. The reflex action of the mind which causes laughter and squirming when some one else tickles you only acts when it is not conscious of the cause.

The whole purpose of the sensitive organization of our skins is to give us information and cause action which will enable us to protect ourselves when any outside influence touches us. An injurious touch causes shock and pain, and the harmless tickle arouses the laughing and squirming sensation.

What Happens When We Laugh?

Laughter is what we call a reflex action. When something occurs to make us laugh, whether it is something we see, or feel, or hear, it is because certain sensory nerves receive an impression in one of three ways, carry it to the nerve centre and the nerve centre then sends the same impression along certain efferent nerves, which connect with certain muscles or glands, and excite them to activity. The action is practically the same as when you hold a light before a mirror. The rays from the light strike the surface of the mirror and are reflected back from the surface, lighting perhaps corners of the room, which the direct rays from the light could not reach, all depending upon the angle of reflection. Light will always reflect from a mirror that is exposed to it.

Now, then, when you see, hear or feel anything that makes you laugh, the sensory nerves have only to receive the impression to bring on the explosion of laughter. Something touched the laugh nerves or the laugh trigger that caused it to go off. You can prove that it is a matter of impression entirely by noting that some people can listen to a perfectly funny story, even when told by a clever performer, and never crack a smile, while others burst into uncontrollable laughter, and he who does not even smile may be listening even more intently than the other--he may even be looking for a laugh. It all depends upon the impression that is made upon the nerves. The muscles have the power to express the state of gladness which is indicated by laughter when certain impressions pass along the nerves which operate them, just as they can be made to do other things when the proper cause for action is shown them.

Why Do We Cry When Hurt?

We cry when we are hurt for the same reason that we laugh when we are glad. The muscles and nerves, under the direction of the brain, produce the cry just as the muscles and nerves produce laughter, although they are probably, but not necessarily, a different set of muscles and nerves.

When we are hurt in any part of our body or feelings the impression does not affect us until it reaches the brain. Then instantly, of course, the body and brain go to work to destroy the pain. The first thing, of course, is to give a warning to other parts of the body that there is a hurt, and our crying is a warning to other people that we are hurt. That is probably the only good that crying does. It does not remove the hurt--it only tells others of our troubles. We cry with the lower part of the brain--the only portion of the brain which is active in a little baby. This is why even a tiny baby can cry. Crying is the only thing a baby can do to give warning of its distress or discomfort. Later in life the upper part of the brain develops. This is the master of the lower part. Therefore, we do not always cry when hurt as we grow older, because the master brain sometimes tells the lower brain that to cry will not help matters in the least, even though we are inclined to cry. Sometimes the hurt or shock to older people is so great or sudden that we cry out before the controlling part of the brain has had time to get in its work of preventing the outcry, but we are able to stop crying when the master brain again secures control.

Where Do Tears Come From?

Tears are not made only when we cry. They seem to come only when you cry, because it is then that they spill over. A little part of you is making tears all the time, and your eyes are constantly washing themselves in them. You have often noticed how you wink every few seconds? You have often tried to keep from winking--to see how long you could keep from winking. Boys and girls often do that, and when you keep from winking what seems a long time, you notice how your eyes ache and feel very dry just before you have to let them wink, in spite of how hard you try not to, and just when you think you are not going to. I will tell you just what winking does for the eyes. All of the time your eyes are open the front, or the part you see things with, is exposed to the dust and dirt that fills the air at all times, although we cannot always see the dust. The wind, too, is constantly making them dry. But have you ever noticed that although you never wash the inside of the front of the eye, or pupil, it is always clean? Well, it is because your eye washes itself every time you wink. I will tell you how this is done. Up above each eye, inside, of course, there is a little gland called the tear-gland. This gland is busy all the time you are awake making tears. As soon as the front of your eye becomes dry, or if a particle of dust or anything else strikes it, the nerves you have there tell the brain, and almost at once the eyelid comes down with a tear inside of it, and so washes the front of your eye clean again. It does its work perfectly and as often as necessary. There is always a tear ready to be used in this way.

Where Do the Tears Go?

Let me show you. Look right down here at the inner corner of my eyelid, where you will see a little hole. That is where the tears get out of the eye, when they have washed your eyeball clean. Where do they go then? Did you ever notice how soon after you cry you have to blow your nose? The reason for that is that when the tears go through the little hole they run down into the nose. This making of tears and winking goes on all the time while you are awake, and after they wash your eye off they go on out through this little hole. But when you cry you make more tears come than you need, so many, in fact, that they cannot all get away through this little hole, and as there is no place else for them to go, and as there is no place to keep them inside the eye, they simply spill themselves right over the edge of your lower eyelid and run down your cheek.

Story in a Barrel of Cement

What Is Cement?

The dictionary tells us that cement is “any adhesive substance which makes two bodies cohere.” Thus any material performing this function may be called cement, such, for example, as the cement used in mending broken china. Glue also is a form of cement. This story has to do with Portland cement, which is a structural or building material used in countless ways.

Why Is Cement Called Portland Cement?

After being wet with water it hardens into stone, and it was given the name “Portland” because, when first manufactured in England, and mixed with sand and stone, it resembled a celebrated building stone called Portland, which was obtained from the Isle of Portland. Compared with other American industries, the manufacture of Portland cement is of recent origin. Formerly all Portland cement was brought from foreign countries. After successful manufacture became established in this country, however, the industry advanced with great rapidity. A few years ago the entire United States did not use as much cement as is now used in any one of our large cities. At the time these facts were written (1914) the manufacturers were making more than 90 millions of barrels a year.

What Is Cement Made Of?

Portland cement is composed chiefly of lime, alumina and silica. It is manufactured from rocks, marl, clay and shale containing these ingredients. If any one of them is lacking in the raw material as it is taken from the earth, it is supplied during process of manufacture. The greatest cement district in America is in Pennsylvania, and is known as the “Lehigh District.” A rock containing proper constituents for making Portland cement was found there in vast quantities, and for a number of years the Lehigh District was the center of the industry. In time it was found that certain clays, marls and shale could also be manufactured into Portland cement, and thus mills have been erected in all sections of the United States. One of the largest companies in the United States found that cement could be manufactured from a combination of blast-furnace slag and limestone, and this is now made by the company in large quantities, the product being a true Portland cement.

What Is Concrete?

Portland cement is the strongest and most lasting of all modern mortars or binding materials. When mixed with sand and stone the resulting mixture is called concrete. Being a plastic material when first mixed, it cannot be used as we use brick or stone, but must be poured into molds or forms, which hold it in place until it hardens into rock. It may be cast in any form or shape, and thus it is useful for a vast number of purposes. It will harden under water, and time and exposure to the elements merely increase its strength. The most common form in which it is used, one familiar to everybody, is in the construction of sidewalks. It is used in all great engineering projects, such as the building of dams, bridges, retaining walls, sewers, subways and tunnels. Being fireproof, large quantities of it are used in buildings and likewise on our farms, where it is extremely valuable as an enduring and sanitary material.

What Is Cement Used For?

It has been said that concrete is a plastic material, meaning that it is soft and pliable in the sense that clay or putty are plastic. For this reason it is cast in forms or molds. Sometimes it is used in the form of plain concrete, and on other occasions it is reinforced, meaning that iron rods, steel bars or woven wire mesh are imbedded in the concrete. When we speak of a “reinforced” concrete building, imagine a huge wire bird cage encrusted within and without with concrete. Place a block, beam or column of concrete upon the ground and it will bear a tremendous load, meaning that it has great strength in compression. On the other hand, if we were to place a long beam upon supports at either end, leaving the greater length of it suspended and without support, it would

carry but a small load compared with concrete in compression. Therefore, in making concrete beams or girders in a building, strong steel bars are embedded in the concrete to take up what are termed the tensile strains.

[Illustration: WHAT A CEMENT MILL LOOKS LIKE

This is a picture of a cement mill. Millions of dollars are invested in these great mills, which are now located in practically all sections of the country. Material is brought from the quarry to the mills, where it passes through various stages, such as grinding, burning and bagging. Expert chemists are employed to see that the cement is made exactly right. It is a very scientific matter to make a thoroughly good cement. There must be no guess work. Some mills are very large, the plant comprising a number of buildings, and some companies operate several mills in different localities. A single company supplied all of the cement used in the Panama Canal, which great project required more than six million barrels.]

[Illustration: This picture shows a quarry in the famous Lehigh cement district. The giant steam shovel or excavator burrows into the hill like some great animal, and when the bucket is full it is dumped into the cars shown on the track, which convey the rock or the raw material to the mill.]

[Illustration: WHERE THE MATERIAL IS OBTAINED

This is an illustration of a method of excavating and loading marl and clay to be manufactured into Portland cement. The large bucket suspended over the cars does not gouge into the hillside as shown in the preceding picture, but descends like a huge steel hand, the metal parts opening and closing like fingers. The long derrick elevates the bucket and swings it over the train of cars.]

[Illustration: This is a view of a powerful rock crusher, which is operated by the electric motor shown at the right. The cement rock is brought from the quarry and dumped into the machine, from which it issues in broken fragments, as shown in the illustration, this being the first or preliminary crushing process.]

[Illustration: THE HUGE ROCK GRINDERS

This is a view of the electric motors operating the grinding machines which reduce the raw material to a very fine powder. There are various types of mills or grinders, to which the material comes after going through the rock crusher. They grind it in preparation for the kilns.]

[Illustration: The kiln is a very important feature of the cement plant. The finely ground raw material must be calcined or burned before it becomes Portland cement. These kilns range from 60 to 240 feet in length. They are slightly inclined and revolve upon rollers. The finely ground material enters the kiln at the upper end and travels throughout its length as the kiln slowly revolves. Powdered coal dust is fed into the kiln at the lower end, where it is ignited and generates intense heat. When the finely ground raw material comes into contact with the heat, which reaches 2800 degrees F., it is transformed into what is known as clinker, which issues from the lower end of the kiln and is passed on to other machinery, which grinds it into impalpable powder or Portland cement.]

[Illustration: HOW CONCRETE IS MIXED

This is an ingenious machine which bags and weighs the cement. The bags are suspended as shown, and when filled and weighed by the machine are placed in barrels and shipped to their destination. Every device of this kind that will save time and labor cheapens the cost of manufacture.]

[Illustration: In mixing cement, sand and stone together in order that concrete may be obtained, it is customary to use, if the operation is a large one, what are known as mechanical mixers. These are large iron cylinders into which the three materials are put and water added. The cylinder or iron drum revolves until the contents are thoroughly mixed, when they issue from the mixer through a chute or spout. A mixer of this type is shown on a succeeding page describing the making of a concrete road. This picture shows mixing concrete by hand. The sand and cement are first thoroughly mixed in the dry state and subsequently the stone and water are added. Concrete should be thoroughly mixed in order that every grain of sand may be entirely coated with cement, and then these two combined make a rich mortar, which should surround entirely every piece of stone.]

[Illustration: HOW CONCRETE BUILDINGS ARE MADE

This picture shows how concrete houses or walls are built through the use of what are known as forms. In building a wall we have an inside and outside form, as shown in the picture, between which the concrete is placed. After it hardens the forms are removed.

In some operations, such as the construction of a large factory building or great bridge, there is such a vast array of timber construction as to make the scene quite impressive, especially when bridge arches of great span and height are under construction.]

[Illustration: This is a view of an arch built of concrete during the Jamestown Exposition. It is a striking illustration of how concrete may be used for both ornamental and practical purposes. In no field has concrete proved to be of more value and economy than in the construction of bridges, whether large or small. Some of the largest bridges in the world are built of concrete, and in many cases iron bridges are incased in concrete to keep them from rusting.]

[Illustration: CONCRETE HOUSES CANNOT BURN

This is a curious example of concrete construction. It is a coal pocket, from which locomotives are supplied with fuel. Railroad companies have adopted it because of its great strength and durability.]

[Illustration: Just as mammoth structures are created with poured concrete, so we may produce the most delicate and ornamental patterns. These are usually cast in plaster molds and often in molds of wood or iron. Where undercut work is required, such as in the sun-dial shown, a wood or metal mold could not be removed without injury to the concrete, and so sculptors have invented the pliable glue mold, which can be easily removed and which will spring back to its original shape if necessary to use it a second time.]

[Illustration: Concrete in dwelling construction means the elimination of fire danger and also cost of painting and repairs. This picture shows a solid concrete house, parts of which have been encrusted with beautiful tiles. Concrete has been successfully used in all types of dwellings, from the humble abode of the workingman to the palace of the multimillionaire. An entire house may be made of concrete, even to the roof and stairways, and where a dwelling is constructed of this material throughout, it is proof against fire and decay.]

[Illustration: HOW THE FARMER USES CONCRETE

This is an interesting example of concrete construction. It is a large water tower which will never warp, rust or decay. In this field concrete has been of great service, whether reservoirs are constructed in the form of towers or tanks. As already stated, water does not affect the life or strength of concrete, except to improve it.]

[Illustration: This is a concrete silo. A silo made of concrete is merely a huge stone jar in which green food for cattle is preserved. The crop is gathered and placed in the silo, thus insuring abundance of green and wholesome food throughout dry seasons and during the winter. The contents of the silo is known as silage or ensilage, and is merely corn fodder cut when green. Concrete silos are both storm- and fire-proof.]

[Illustration: It is usual to consider concrete in connection with great engineering enterprises, but nevertheless many millions of barrels are used each year by the farmers of the United States. This picture shows a clean, sanitary and durable concrete stable. In buildings of this character concrete is rapidly supplanting wood, which soon goes to decay, to say nothing of accumulation of filth.]

[Illustration: HOW CONCRETE ROADS ARE BUILT

MECHANICAL CEMENT MIXER]

[Illustration: A CONCRETE ROAD

Our two last pictures relate to an exceedingly important and rapidly increasing use of cement. It is the construction of concrete roads. The first picture shows a concrete road in course of construction. The mechanical mixer referred to above is shown in this picture. It is a self-propelling machine and mixes the concrete very rapidly. As it comes from the mixer in a wet and mushy mass it is placed between rigidly staked side forms, where it hardens into imperishable rock. The road is brought to its shape by working to and fro a long plank called a template, after which the surface of the road is troweled with wooden floats, giving it a texture which prevents horses and cars from slipping. The last picture shows a narrow concrete road in the state of Maryland. Wherever these roads have been built they mean much to the women and children of the community. They never grind up into mud or dust, and are as pleasant to walk upon as the sidewalks of the city. Children, especially, delight in them. In Wayne county, Mich., where they have the most celebrated concrete roads in the world, the children go to and from school on roller skates, and various games are played on the concrete road.]

Why Don’t We Make Roads Perfectly Level?

Roads are made with a curving upper surface, i. e., higher in the middle, in order that the rain will drain away from the road into the gutters or ditches which you find at the sides. You see water has the faculty of running only in one direction, and that is downward. If it cannot go down on one side or the other, it will collect in puddles and make the road impassable. For this reason we build our roads so they are higher in the middle than at the sides--not much higher; only about six inches or so--giving them just the gentle slope toward each side that is necessary to allow the water to run off gradually, but sufficiently sloping to keep the water from collecting in puddles in the road. Thus after the dust has been settled by the first rain that falls, most of the surplus rain that falls on the roads finally runs into the ditches at the side of the road.

Why Are Some Roads Called Turnpikes?

Undoubtedly the name turnpike as applied to some roads arose from the fact that pikes or gates were set across the roads by the keeper or toll-collector. In addition to collecting tolls, it was a part of the toll-keeper’s business to keep the road in repair. His wages and other expenses for doing this were received from the tolls collected from the people who used the road to ride on in carriages, wagons, etc. In the early days the toll-collector was armed with a pike, a long-handled weapon with a sharp iron head, which he used to prevent people who travelled his road from going by without giving up their toll. Later on a swinging gate was built across the road, which made it unnecessary to use the pike, though the name was retained, for no one could pass while the gate barred the way. When the passerby had paid his tolls, the toll-collector opened the gate and let him pass. If he did not pay the gate remained closed and the driver had to turn back or decide to pay. Hence comes the name turnpike. In some parts of the country they call these toll roads.

What Is Dust?

A large part of the dust we see in the roadway when the horses kick it up, or when an automobile passes, is made up of the pulverized dirt of the roadway. It becomes mixed with other things, such as the street deposits of animals, particles of carbon, etc. Particles of this dust get into our throats, and as there are many germs in it, they are very liable to cause sickness, especially the colds from which we suffer.

What Becomes of the Dust?

The dust of the roadway is generally blown away by the wind, to come down to earth again wherever the wind happens to carry it--on the lawns, the doorsteps or back to the road, perhaps. In any event, the rain which is certain to come sooner or later, washes this dust back into the soil, or into the sewers. Part of it mixes with the soil. The organic matter in dust helps to fertilize the soil, and is therefore useful. Other parts of the dust are oxidized and consumed by the air, through the heat of the sun. So you see the dust is continually changing from one thing to another.

Are Stones Alive?

Real stones are not alive. They do not become stones until they have been burned out--until they have become what is known as dead matter. This is meant entirely in the sense that we commonly think of the meaning of the word “alive,” which is to be able to breathe and grow. Stones can neither breathe nor grow. They belong to the inanimate kingdom of things on the earth. Particles of this dead matter, found in stones, etc., are in many cases taken up by things that are actually alive, and help to form the bodies of living things.

The most common thing to be found in rocks and stones is what is called “silicon,” and we find this silicon in the straws of the wheat, oats and corn, and in many other things, but not in a way that can be detected except by chemical analysis. A great many of the things found in stones are found in living things, but rocks and stones are not alive in any sense.

What and Why Is Smoke?

Smoke is produced only when something which is being burned is burning imperfectly. If we were to put anything burnable into the fire and establish just the right amount of draft, and knew how to build our fires properly, there would be no smoke and very little

ashes.

In the case of the black coal smoke which we think of mostly when we think of smoke at all, the black portion is principally little unburned particles of coal which pass up the chimney with the gases which are thrown off when the coal is being burned. These gases would be invisible--they really are invisible--if it were not for the little particles of coal which are drawn up the chimney with them. If you look at the chimney from which a wood fire expels the gases you find the smoke very light in color--showing that not so much unburned matter is being thrown off. A charcoal fire makes no smoke, because the charcoal has had the unburnable things taken out of it beforehand, and the charcoal stove is almost perfect in construction from the standpoint of combustion.

Of course, the thickness of the smoke from a coal fire is often increased by the fact that there are unburnable things mixed in with the coal, some of which also pass off through the chimney.

Why Can't We Burn Stones?

We cannot burn anything that has already been burned, and a stone has already been burned. To understand how this is we must first find out what takes place when a thing is burned. When a thing is burning it means merely that that particular thing is taking into its system all of the oxygen of the air that it can combine with. When it has done this it cannot be burned any more. Of course, in doing this the thing originally burned changes its character. The elements in a candle when lighted mix with the oxygen in the air and disappear in the form of gases. The elements in coal mix when fired with oxygen and change into ashes, gases and smoke. A stone, however, is the result of a burning that has already taken place. The original element of most of the rocks and stones we see was silicon, and when that combines with oxygen, the result is some form of rock, which you may be able to break up or throw, but which you cannot burn again.

What Is Fog?

The fog which we generally think of when we speak this word is the fog at or on the sea or other body of water--the one that makes the ships stand by and blow their fog horns. A fog of this kind is nothing more nor less than a cloud, come right down to earth and spread out a little more. People who have gone up into the air in balloons and other airships through the clouds, say that the clouds are only fogs, and that above them it is as clear as it is on a sunshiny day on the water when there is no fog.

There is another kind of fog which settles down over the land, especially in the cities. It is a damp mist which combines with the smoke and other impurities in the air and forms a black and dirty cloud about everything. This occurs when the upper air prevents the smoke which rises from a city with all its people and fires in the furnaces from passing up and away. The upper air acts like a blanket and keeps the misty, smoky air down, until the wind comes along and blows it away.

What Becomes of the Smoke?

There are a number of things in smoke, and when we know what they are, we will find a natural answer to this question. First, there are, of course, the little unburned particles of fuel which get carried up the chimney by its drawing power. These naturally fall to the ground of their own weight, once they get beyond the drawing power of the chimney and out of the current of air so formed. Some of the gases are already quite burned out when they pass up the chimney. There is a lot of carbonic acid gas which, of course, mixes with the air and eventually becomes food for the plants. Then there are some gases which are not entirely burned, and the air burns them still more until they, too, become carbonic acid gas, or water which is also thrown off by a burning fire.

Why Does an Apple Turn Brown When Cut?

The reason is that when you cut an apple, the exposure to the air of the inside of the apple causes a chemical change to take place, due to the effect the oxygen in the air has on what is scientifically known as the enzymes in the apple, or what are commonly called the "ferments." When the peel is unbroken it protects the inside of the apple against this action by the oxygen. The brown color happens to be due to the chemical action. The action is similar to the action of the air on wet or damp iron or steel, in which case we call it rust.

Why Does a Piece of Wood Float in Water?

A piece of wood will float in water because it is lighter than the same amount of water. We do not mean that a piece of wood weighing one pound, for instance, would weigh any more than a pound of water, of course, but if you took the measurements of each you will find that it took less bulk to make a pound of water than of wood. If you had a piece of wood so shaped that it just filled a glass completely, and then took another glass and filled it with water, you would find that the glass containing the water weighed the most. Another name to give to this difference would be to say that the water was more dense than the wood. By the law of gravitation the denser thing will always go to the bottom, and as wood is less dense than water, it will stay at the top if put in water. The piece of wood has more air in it than the water. If you could expel the air from the piece of wood and then put it in water, it would sink.

Why Does Iron Sink In Water?

The explanation in regard to the piece of wood floating in water is the beginning of the answer to this question. A piece of iron is heavier than an equal bulk of water, and will therefore go to the bottom, as will all things which are more dense than water. A piece of iron has no air in it. The particles of a piece of iron are so close together that there is no room for air in it and it will therefore sink in water. A piece of wood from which all of the air had been expelled would also sink.

Why Doesn't an Iron Ship Sink?

This is a very natural question for you to ask right after you were told why iron sinks in water. The explanation is that by making an iron ship in the way we do, we fix it so that it holds a lot of air in between the bottom and sides, making the combination of the two--the iron ship and the air in it--lighter than the water on which it sails. Men thought at one time that a ship would sink if made of iron, and therefore built all of their ships of wood. Finally one inventor made a ship of iron and it was one of the wonders of the world. When we found that iron ships would float if they were built to retain sufficient air to keep them from sinking, we made the hulls of most ships of iron for a time. Now, however, the best ships are made of steel, which is even better.

If you bore a hole in the bottom of a ship, the water will run in if the ship is in the water, and the ship will sink, because the water coming in drives out the air; and when the ship is full of water, the water in it, with the ship itself, are heavier than the water on which it sails, and the ship will go down. Filling a ship with water makes the iron part of the ship just like a bar of iron, so far as its sinking qualities are concerned.

Of course, an iron ship must be made long enough and broad enough so that when it is completed there will be sufficient air contained within the hull to make the combination lighter than water. Always, therefore, when a ship is to be built, competent engineers must go over the plans of the vessel and calculate the air capacity, so as to make sure she will float.

Nowadays it would be difficult to sink a modern vessel by boring one small hole in the bottom, because the bottom and sides are lined with enclosed steel air-chambers, and a ship will keep afloat even if one or a number of holes are made. The reason is, of course, that when you bore a hole into one of these air-chambers the water rushing in will fill that air-chamber with water, but as there is no connection from the inside with the rest of the ship, the water can get no further.

Why Does a Poker Get Hot at Both Ends if Left in the Fire?

Both ends of the poker become heated because the poker is made of iron, and iron is a particularly good conductor of heat. To understand this we must look into the question of what a good conductor of heat is. In this case the particles of iron, which combined form the poker, are so close together that when those at the end of the poker which is in the fire get hot, the particles at that end hand the heat on to the particles next to them, and so on until the whole poker is hot. The difference between a thing which is a good conductor of heat and a thing which is not a good conductor, lies in the ability of the different particles which compose it to hand the heat on to the others. Did you ever notice that the handle of a solid silver spoon will become hot if the spoon is left in hot coffee? Solid silver is a good conductor of heat. A plated spoon is not a good conductor, however, and will not become hot if left in the cup of hot coffee as a solid silver spoon will.

Would a Wooden Spoon Get Hot?

A wooden spoon would not get hot, because wood is not a good conductor of heat. The atoms which compose the wood have not the power to transmit the heat to each other. This is strange, too, when we think that a poker is a good conductor of heat, but will

not burn, while wood is not a good conductor, but will burn readily. Perhaps you have already discovered this in connection with a wood fire. One end of a stick of wood may be burning fiercely, and yet you can pick it up by the other end and find it is not even warm. This proves to you that wood is not a good conductor of heat, and explains why the handle of a wooden spoon in a bowl of hot soup will not get hot while the handle of a silver spoon will.

Why Does Iron Turn Red When Red Hot?

The answer is that the piece of iron has been heated to the point where it gives off light of its own. The red you see is only one stage in the development of iron to the point where it makes its own light. If you heat it still more it will make a white light. You know that it produces the light itself, because if you take a piece of iron into a perfectly dark room and heat it to a white heat it will show better than where there is other light. If you continue the process the iron will melt and change in form. Therefore, the “red hot” name for a piece of iron in that state is a perfect name. It is a warning that the iron is coming to a point where if the heating process is continued, it will change its form and in this state, when treated according to known methods, the iron is turned into steel, which has many characteristics that iron does not possess. Now, I can, of course, hear you ask why doesn’t an iron kettle get red hot? and I can answer that easily. If you treat the kettle the same way as you do the piece of iron, it will get red hot. The difference is that you are thinking of an iron kettle with water in it. As long as there is any water in the kettle, that keeps it from getting hot. The water inside keeps the kettle from becoming red hot. If you took a hollow rod of iron and filled it with water, it would not become red hot as long as any water remained in the hollow portion.

How Did the Sand Get on the Seashore?

The sand on the seashore is nothing more or less than ground-up sandstone. In dealing with the inanimate things in the world we find that a very important element of all of them has been given the name silicon. When the crust of the earth, which is the part we call the land and rocks, and includes the part under the sea, was a molten mass, this silicon was burned, combining with the oxygen which surrounded everything, and produced what is known as silica. Silica is the name given to the thing which is left after you burn silicon. A very large part of this silica was deposited in parts of the earth, and when the crust of the earth cooled off it was sand. By pressure and contact with other substances it became stuck together, just as you can take wet sand at the seashore to-day and make bricks and houses and tunnels, excepting that in the case we speak of it was something besides water that pressed and stuck the little particles of sand together. They stuck together more permanently. Then when the oceans were formed, as shown in another part of this book, much of the sandstone was found to be at the bottom and on the shores of the oceans. The action of the water continually washing against the sandstone gradually broke the sandstone up into the tiny particles of sand again, and this is what makes the sand on the seashore.

What Makes a Soap Bubble?

A bubble is merely a hollow ball of water with air inside. The air in coming up through the water in trying to rise out of the water is caught in the water in such a way as to form the bubble, and since the ability of the air inside of the bubble to rise is greater than that of the water which forms the bubble, and which has a tendency to pull it down, the bubble rises into the air. The water ball is very thin and keeps running down to the bottom of the ball, where you see it form into drops, and soon this makes the walls of the water bubble so thin that the air bursts through the ball of water, and that is

What Makes the Bubble Explode?

Sometimes we blow soap bubbles. We mix soap in the water and that makes the walls of the water ball which we produce a little tougher, and it requires a great deal more effort for the air to escape from it, as the soap keeps the water in the walls of the bubble from running down to the bottom for quite some time, and, therefore, soap bubbles will often travel in the air for some distance. The colors we see on soap bubbles are produced by the rays of sunlight, which strike the bubble and reflect them back to us in colors very similar to those of the rainbow.

Why Are Bubbles Round?

Bubbles are round because the air which forms the inside of the bubble exerts an equal pressure in all directions. It presses equally against all sides of the bubble at the same time.

The Story in a Yard of Silk

God's Creation and Man's Invention.

~WHERE DOES SILK COME FROM?~

Silk in its finished state is an ideal product. It is at once durable, magnificent to the eye, tender to the touch, and its rustle is soft music to the ear. Hence it is easy to understand why the silkworm, from the earliest times, has been an object of much consideration and concern from a commercial and industrial point of view. In this country alone, we annually expend as much for silk goods as we do for public education and thirty times as much as we do for foreign missions. Such an indomitable producer of wealth is the silkworm, and a producer of wealth it has been from an age as remote as when Joseph was down in old Egypt, interpreting the dreams of King Pharaoh's butler and baker and later that of the King himself.

To-day we speak of twenty centuries, and our minds can hardly comprehend such a lapse of time. What shall we think of the silkworm, that for twice twenty centuries has furnished practically all the raw material for the world's silk supply? Because man's ingenuity is at present actively engaged in the attempt to displace it by cheaper substitutes, the thought has come to us that, without going too minutely into mechanical processes, a good opportunity is presented to give some interesting information in regard to the silkworm as the creation of the Divine Hand, in contrast to the silkworm as the creation of man.

According to Chinese authority, the use of silk dates from 2650 B.C., and it is generally conceded that, in point of age, it stands midway among the great textiles, wool and cotton having preceded it, while flax, hemp and other fibrous plants followed shortly in its train.

The first patron of the silkworm was Hoang-Ti, Third Emperor of China, and his Empress, Si-Ling-Chi, was the first practical silkworm breeder and silk reeler. It is related of her that she was once walking in the palace gardens when she discovered a strange and repulsive looking worm. It was small, of a pale green color, and was feeding greedily on a mulberry leaf. She interested the Emperor in this strange creature, and, at the Emperor's suggestion, took the fine silken web which the worm finally spun, and was the first to successfully reel the new filament and weave it into cloth. So beneficial to the nation was her work considered that her gratified subjects bestowed upon her the divine title of "Goddess of the Silkworms," and to this day the Chinese celebrate in her honor the "Con-Con Feast," which takes place during the season in which the silkworm eggs are hatched.

In accounting for the presence of silkworms in the garden of this early empress, we can rightly conclude that certain parts of China have always abounded in forests of mulberry trees, and that the worms themselves had existed in great numbers in a wild state and attached their cocoons to the trees for ages before any use was discovered for their web. In fact, such wild silkworms not only abound in China to-day, but have also been found in Southern and Eastern Asia, inhabiting the jungles of India, Pegu, Siam and Cochin China, but the cocoons of these worms are, naturally, of a very inferior quality, and are only used for the crudest kind of work.

THE INTRODUCTION OF SILK INTO EUROPE

Pilgrims brought silkworm eggs in their staffs, together with the branches of mulberry trees, from China to the Court of Justinian at Byzantine, A.D. 555. The penalty for taking silkworm eggs out of China was death.

The accompanying illustration is a reproduction of a mural painting on rep in the Royal Textile Museum at Crefeld, Germany, one of the great silk textile centers of the world. The artist shows the pilgrims presenting the silkworm eggs and the mulberry branches to Justinian, beside whom, just in the act of rising, is his famous queen Theodora.]

Silk culture from the time of Hoang-Ti became one of the cherished secrets of China. The headquarters of the industry was in the Province of Chen Tong, where was produced the silk for the royal family. In time the silk and stuffs of China became articles of export to various portions of Asia. Long journeys were made by caravans, occupying two-thirds of a year in going from the cities of

China to those of Syria, but the price obtained there exceeded the expense of the journey, and thus left a large margin of profit to the merchants. In this manner, for one thousand years, the Chinese sent their silk to the Persians who, without knowing how or from what it was made, carried it to the Western nations.

So carefully did the Orientals guard their secret, that there is reason to believe that Aristotle was the first person in the occidental world to learn the true origin of the wrought silk from Persia. In commenting on the silk which was brought from that country on the return of Alexander's victorious army, he described the silkworm as a "horned insect," passing through several transformations, which produced "bomby-kia," as he called the silk. But the classics must convince one that Aristotle's discovery did not at once become matter of current knowledge. In fact, for five hundred years after Aristotle's time the common theory of the origin of silk among the Greeks and Romans was that it was either "a fleece which grew upon a tree" (thus confounding it with cotton), or a fibre obtained from the inner bark of a tree; and some, deceived by the glossy and silky fibres of the seed vessels of the plant that corresponds to our milk or silk weed, believed it to be the product of some plant or flower. So Virgil, in speaking of silk, says, "the Seres comb the delicate fleecings from the leaves."

In the Sixth Century, A.D., all the raw silk was still being imported from China by way of Persia, when the Emperor Justinian, having engaged in war with Persia, found his supply of raw silk cut off and the manufacturers in great distress. His foolish legislation did not help the situation, and a crisis was averted only by two Nestorian monks, who came from China with seed of the mulberry tree and a knowledge of the Chinese method of rearing worms. No one, on pain of death, was allowed to export the silkworm eggs from China, but Justinian bribed the monks to return to that country, and in 555 they came back, bringing with them a quantity of silkworm eggs concealed in their pilgrim's staffs. And here let us say that there has only once since been an important importation of eggs from Asia. That was about 1860, when Dr. Pasteur was making a study of a germ disease which was threatening the industry. Consequently, it can truly be said that practically all the silkworms of the Western world are descended from those brought in the eggs by the monks to Constantinople. Justinian gave the control of the silk industry to his own treasurer. Weavers, brought from Tyre and Berytus, were employed to manufacture the silk, and the whole production was a monopoly of the emperor, he fixing its prices. Under his management, the cost of silk became eight times as great as before, and the Royal Purple was twenty-four times its former price. But this monopoly was not of long duration and, at the death of Justinian in 565, the monopoly ceased, and the spread of the industry commenced in new and diverse directions.

While every detail of the growth of the industry has an unusual interest, as showing how such an insignificant thing as a worm may become a potent factor in Nature's economy, the scope of this article will hardly allow us to more than sketch some of the other more salient points of the history of the silkworm.

About the year 910, the silkworms made their appearance in Cordova, Spain, being brought there by the Moors. From Spain silk culture soon extended to Greece and Italy.

~WHEN SILK CULTURE WAS INTRODUCED IN AMERICA~

Silk was introduced on this continent through the Spanish Conquest of Mexico, and the first silkworm eggs sold for $60.00 an ounce.

A century later royal orders were issued requiring mulberry trees to be planted in the Colony of Virginia, and a fine of twenty pounds of tobacco was imposed for neglect, and fifty pounds of tobacco was given as a bounty for every pound of reeled silk produced.

Silk culture spread rapidly in the other Colonies, and to-day the story of the ineffectual attempts to profitably rear the silkworm in this country is as voluminous as it is interesting. Suffice it to say, as a sop to our inherent Yankee pride, that silk culture was introduced into Connecticut as early as 1737, the first coat and stockings made from New England silk being worn by Governor Law in 1747, and the first silk dress by his daughter, in 1750. This State, for the eighty-four years following, led all the others in the amount of raw silk produced. In Connecticut also, was built the first silk mill to be erected on this continent for the special purpose of manufacturing silk goods. This building was constructed in 1810 by Rodney and Horatio Hanks, at Mansfield, and is still standing as an heirloom which has come to us from the infant days of the industry.

The silkworm has become domesticated, since, during the long centuries in which it has been cultivated, it has acquired many useful peculiarities. Man has striven to increase its silk producing power, and in this he has succeeded, for, by comparing the cocoon of the silkworm of to-day with its wild relations, the cocoon is found to be much larger, even in proportion to the size of the worm that makes it or the moth that issues from it. The moth's loss of the power of flight and the white color of the species are

probably the results of domestication.

[Illustration: SIDE VIEW OF CHRYSALIS.[2]]

[Illustration: BOTTOM VIEW OF CHRYSALIS.[2]]

[2] The cuts on this page and balance of cuts in the story of silk copyright by the Corticelli Silk Mills.

The silk moth exists in four states--egg, larva, chrysalis, and adult. The egg of the moth is nearly round, slightly flattened, and closely resembles a turnip seed. When first laid it is yellow, soon turning a gray or slate color if impregnated. It has a small spot on one end called the micropyle, and when the worm hatches, which in our climate is about the first of June, it gnaws a hole through this spot. Black in color, scarcely an eighth of an inch in length, covered with long hair, with a shiny nose, and sixteen small legs, the baby worm is born, leaving the shell of the egg white and transparent.

~THE SILKWORM—HOW HE DOES HIS WORK~

Small and tender leaves of the white mulberry or osage orange are fed the young worm which simply pierces them and sucks the sap. Soon the worm becomes large enough to eat the tender portions between the veins of the leaf. In eating they hold the leaves by the six forward feet, and then cut off semi-circular slices from the leaf’s edge by the sharp upper portion of the mouth. The jaws

move sidewise, and several thousand worms eating make a noise like falling rain.

The worms are kept on trays made of matting, that are placed on racks for convenience in handling. The leaves are placed beside the worms, or upon a slatted or perforated tray placed above them, and those that crawl off are retained, while the weak ones are removed with the old leaves. The worms breathe through spiracles, small holes which look like black spots, one row of nine down each side of the body. They have no eyes, but are quite sensitive to a jar, and if you hit the rack they stop eating and throw their heads to one side. They are velvety, smooth, and cold to the touch, and the flesh is firm, almost hard. The pulsation of the blood may be traced on the back of the worm, running towards the head.

The worm has four molting seasons, at each of which it sheds its old skin for a new one, since in the very rapid growth of the worm the old skin cannot keep pace with the growth of the body. The periods between these different molts are called “ages,” there being five, the first extending from the time of hatching to the end of the first molt, and the last from the end of the fourth molt to the transformation of the insect into a chrysalis. The time between the four “molts” will be found to vary, depending upon the species of worm.

[Illustration: HOW THE SILKWORMS ARE REARED.[2]]

When the worm molts it ceases eating, grows slightly lighter in color, fastens itself firmly by the ten prolegs, and especially by the last two, to some object, and holding up its head and the fore part of its body remains in a torpid state for nearly two days.

By each successive molt the worm grows lighter, finally becoming a slate or cream white color, and the hair, which was long at first, gradually disappears. The gummy liquid which combines the two strands hardens immediately on exposure to the air.

The worm works incessantly, forcing the silk out by the contraction of its body. The thin, gauze-like network which soon surrounds it gradually thickens, until, twenty-four hours after beginning to spin, the worm is nearly hidden from view. However, the cocoon is not completed for about three days.

~SIXTY-FIVE MOTIONS OF HIS HEAD A MINUTE~

The cocoon is tough, strong, and compact, composed of a firm, continuous thread, which is, however, not wound in concentric circles, but irregularly in short figure eight loops, first in one place and then in another. In doing this the worm makes sixty-five elliptical motions of his head a minute or a total of 300,000 in an average cocoon. The motion of the worm’s head when starting the cocoon is very rapid, and nine to twelve inches of silk flow from the spinneret in a minute, but later the average would be about half this amount per minute.

[Illustration: SILKWORM EATING.[2]]

[Illustration: SILKWORM—ONE OF THE WORLD’S GREATEST WORKERS

SILKWORM PREPARING TO FORM ITS COCOON.]

Having attained full growth, the worm is ready to spin its cocoon. It loses its appetite, shrinks nearly an inch in length, grows nearly transparent, often acquiring a pinkish hue, becomes restless, seeks a quiet place or corner, and moves its head from side to side in an effort to find objects on which to attach its guy lines within which to build its cocoon. The silk is elaborated in a semi-fluid condition in two long, convoluted vessels or glands between the prolegs and head, one upon each side of the alimentary canal. As these vessels approach the head they grow more slender, and finally unite within the spinneret, a small double orifice below the mouth, from which the silk issues in a glutinous state and apparently in a single thread.

[Illustration: COCOON BEGUN--SILKWORM CAN STILL BE SEEN.]

The color of the worm’s prolegs before spinning indicates the color the cocoon will be. This varies in different species, and may be a silvery white, cream, yellow, lemon, or green.

[Illustration: COMPLETED COCOON.]

~WHEN THE SILKWORM’S WORK IS DONE~

When the worm has finished spinning, it is one and a quarter inches long. Two days later, by a final molt, its dried-up skin breaks at the nose and is crowded back off the body, revealing the chrysalis, an oval cone one inch in length. It is a light yellow in color, and

immediately after molting is soft to the touch. The ten prolegs of the worm have disappeared, the four wings of the future moth are folded over the breast, together with the six legs and two feelers, or antennæ. It soon turns brown, and the skin hardens into a tough shell. Nature provides the cocoon to protect the worm from the elements while it is being transformed into a chrysalis, and thence into the moth.

[Illustration: MOTHS EMERGING FROM COCOONS.]

With no jaws, and confined within the narrow space of the cocoon, the moth has some difficulty in escaping. After two or three weeks the shell of the chrysalis bursts, and the moth ejects against the end of the cocoon a strongly alkaline liquid which moistens and dissolves the hard, gummy lining. Pushing aside some of the silken threads and breaking others, with crimped and damp wings the moth emerges; and the exit once effected, the wings soon expand and dry.

[Illustration: COCOONS FROM WHICH THE MOTHS HAVE EMERGED.]

The escape of the moth, however, breaks so many threads that the cocoons are ruined for reeling, and consequently, when ten days old, all those not intended for seed are placed in a steam heater to stifle the chrysalis, and the silk may then be reeled at any future time.

The moths are cream white in color. They have no mouths, but do have eyes, which is just the reverse of the case of the worm. From the time it begins to spin until the moth dies, the insect takes no nourishment. The six forward legs of the worm become the legs of the moth. Soon after mating the eggs are laid.

The male has broader feelers than the female, is smaller in size, and quite active. The female lays half her eggs, rests a few hours, and then lays the remainder. Her two or three days' life is spent within a space occupying less than six inches in diameter.

One moth lays from three to four hundred eggs, depositing them over an even surface. In some species a gummy liquid sticks the eggs to the object upon which they are laid. In the large cocoon varieties there are full thirty thousand eggs in a single ounce avoirdupois. It takes from twenty-five hundred to three thousand cocoons to make a pound of reeled silk. Do you wonder that, centuries ago, silk was valued at its weight in gold?

Growers of silk in the United States, by working early and late every day during the season, which lasts from six to eight weeks, could scarcely average fifteen cents for a day's labor of ten hours. Silk, once regarded as a luxury, is now considered a necessity.

[Illustration: HOW THE COCOON IS UNWOUND

REELING THE SILK FROM COCOONS BY FOOT POWER, CALLED "RE-REEL" SILK.

The cocoons are first assorted, those of the same color being placed by themselves, and those of fine and coarse texture likewise. The outside loose silk is then removed, as this cannot be reeled, after which the cocoons are plunged into warm water to soften the "gum" which sticks the threads together. The operator brushes the cocoons with a small broom, to the straws of which their fibers become attached, and then carefully unwinds the loose silk until each cocoon shows but one thread. These three operations are called "soaking," "brushing," and "cleansing."

Into one or two compartments in a basin of warm water below the reel are placed four or more cocoons, according to the size of the thread desired. The threads from the cocoons in each compartment are gathered together and, after passing through two separate perforated agates a few inches above the surface of the water, are brought together and twisted around each other several times, then separated and passed upward over the traverse guide-eyes to the reel. The traverse moves to and fro horizontally, distributing the thread in a broad band over the surface of the reel. The rapid crossing of the thread from side to side of the skein in reeling facilitates handling and unwinding without tangling, the natural gum of the silk sticking the threads to each other on the arms of the reel, thus securing the traverse. Silk reeled by hand or foot power is known as "Re-reel" silk, while silk reeled by power machinery is called "Filature."]

[Illustration: A FILATURE--REELING THE SILK FROM COCOONS BY POWER MACHINERY.[2]]

[Illustration: DRYING SKEINS OF SILK.]

[Illustration: THE SILK IS WOUND ON SPOOLS

WINDING FRAMES--WINDING THE SILK ON BOBBINS.]

~WHERE MAN'S WORK ON THE SILK BEGINS~

The raw silk is first assorted, according to the size of the fiber, as fine, medium, and coarse. The skeins are put into canvas bags and then soaked over night in warm soapsuds. This is necessary to soften the natural gum in the silk, which had stuck the threads together on the arms of the reel. Following the soaking, the skeins are straightened out and hung across poles in a steam-heated room, as shown in the accompanying photograph. When the skeins are dry, they are ready for the first process of manufacturing. The room we now step into is filled with "winding frames," each containing two long rows of "swifts," from which the silk is wound on to bobbins. The bobbins are large spools about three inches long. The bobbins filled with silk, as wound from the skeins, are next placed on pins of the "doubling frames"; the thread from several bobbins, according to the size of the silk desired, is passed upward through drop wires on to another bobbin. Should one of the threads break, the "drop wire" falls, which action stops the bobbin. By this ingenious device absolute uniformity in the size of silk is secured. The "doubling frame" is shown in one of the photographs herewith.

[Illustration: DOUBLING FRAMES--THE SILK THREAD IS MADE UNIFORM.]

The bobbins taken from the "doubling frame" are next placed on a "spinner." Driven by an endless belt at the rate of over six thousand turns a minute, the bobbins revolve, the silk from them being drawn upward on to another bobbin. This spins the several strands brought together by the "doubling process" into one thread, the number of turns depending on the kind of silk--Filo silk being spun quite slack, and Machine Twist just the reverse.

[Illustration: SPINNING SILK.[2]]

[Illustration: TWISTING SILK.[2]]

A transferring machine combines two or three of these strands; two for sewing silk and three for machine twist; and the bobbin next goes on to the "twisting machine"--a machine that is similar to a "spinner," but the silk is twisted in the opposite direction from the spinning. To stand before these machines and watch how rapidly and how accurately they do the work assigned them is a revelation. No one realizes how nicely the parts are adjusted. If but one tiny strand breaks that part of the machinery is stopped by an automatic device which works instantaneously. After twisting, the silk is stretched by an ingenious machine called a "water-stretcher." This smooths and consolidates the constituent fibers, giving an evenness to the silk not to be obtained by any other known process. The bobbins are placed in water and the silk is wound on to the lower of the two copper rolls. From the lower roll it passes upward to the upper roll, which turns faster than the lower one, thereby stretching the silk. From the upper roll it passes again on to a bobbin.

[Illustration: SILK THREADS READY FOR THE WEAVER

WATER STRETCHER--MAKING THE SILK THREAD SMOOTH.]

The dyeing process is a very important one, and upon its success depends the permanency of the various colors.

Vast tubs, tanks, and kettles surround you on every side, and the hissing steam seems to spring from all quarters. The "gum" of the silk is first boiled out by immersion in strong soapsuds for about four hours. The attendants, standing in heavy "clogs" (big shoes with wooden soles two inches thick), turn the silk on the sticks at intervals until the gum is removed. After the silk is dyed it is put into a "steam finisher," a device looking like a long, narrow box with a cover opening on the side, set upright on top of an iron cylinder. The hanks of silk are placed upon two pins in the steam chest, the cover fastened, and the live steam rushes in around the silk. This brightens the silk, giving it the lustrous, glossy appearance.

The editors are indebted to the Corticelli Silk Mills, Florence, Mass., for this story of how silk is made, as well as for permission to use their splendid life-like copyrighted photographs of the silkworm. Many teachers will be glad to know that they can obtain from the Corticelli Silk Mills, at slight expense, specimen cocoons and other helps for object lesson teaching.

What Animal Can Leap the Greatest Distance?

The galago, or flying lemur. This singular animal is a native of the Indian Archipelago. It is from 2 ft. to 3 ft. in length, and is furnished with a sort of membrane on each side of its body connecting its limbs with each other; this is extended and acts as a parachute while taking its long leaps, which measure about 300 ft. in an inclined plane. The kangaroo can leap with ease a distance

of between 60 ft. and 70 ft. and can spring clean over a horse and take fences from 12 ft. to 14 ft. in height. The animals that can leap the greatest distance in proportion to their size are the flea and the grasshopper, the former being able to leap over an obstacle five hundred times its own height, while the grasshopper can leap for a distance measuring 200 times its own length. The springbok will clear from 30 ft. to 40 ft. at a single bound. The flying squirrel, in leaping from tree to tree often clears 50 ft. in a leap. This animal also has a broad fold of skin or membrane connecting its fore and hind legs. A steeplechase horse, called The Chandler, is reported to have covered 39 ft. in a single leap at Warwick some years ago. Some species of antelopes can make a leap 36 ft. in length and 10 ft. in height. A lion and a tiger each clear from 18 ft. to over 20 ft. at a bound while springing on their prey. A salmon often leaps 15 ft. out of the water in ascending the falls of rivers.

Why Do We Call Voting Balloting?

The term covers all forms of secret voting, as in early times such votes were determined by balls of different colors deposited in the same box, or balls of one color placed in various boxes. The Greeks used shells (ostrakon), whence we derive the term ostracism. In 139 B.C. the Romans voted by tickets. The ballot was first used in America in 1629, when the Salem Church thus chose a pastor. It was employed in the Netherlands in the same year, but was not established in England until 1872, although in Scotland it was used in cases of ostracism in the 17th century. In 1634 the governor of Massachusetts was elected by ballot, and the constitutions of Pennsylvania, New Jersey and North Carolina adopted in 1776, made this method of voting obligatory. The ballot progressed slowly in the Southern States, Kentucky retaining the viva voce method until a comparatively recent date. In certain states, the constitutions stipulate that the legislature shall vote viva voce, i. e., cast their votes orally. Since 1875 all congressmen have been elected by ballot. In 1888 the Australian ballot system, which requires the names of all the candidates for the various offices to be placed on one large sheet of paper, commonly known as a “blanket” ticket, was adopted in Louisville, Ky., and some sections of Massachusetts. It is now in very general use in this country. The voter, in the privacy of an individual booth, indicates his preference by making a mark opposite a party emblem or a candidate’s name. This system originated in 1851 with Francis S. Dutton, of South Australia, and Henry George, in a pamphlet, “English Elections,” published in 1882, was the first to advocate it in the United States. The first bill enacting it into a law here was introduced in the Michigan legislature in 1887, but it did not pass until 1889.

Why Do We Call a Cab a Hansom?

The term is applied usually to a public vehicle, known in England as a “two-wheeler,” or “Hansom” (from the name of the inventor), and drawn by one horse. In a hansom cab, the passenger or hirer of the vehicle sits immediately in rear of the dashboard, the driver sitting on an elevated perch behind, the reins being passed over the top. The term cab is sometimes also applied to a four-seated, closed or open carriage, drawn by one or two horses, the driver sitting in front. The term is also applied to the covered part of a locomotive, in which the engineer and fireman have their stations. The word cab is derived from the cabriolet, a light one-horse carriage, with two seats and a calash top. In London, England, the cab or hansom was called the “gondola” of the British metropolis by Disraeli.

Where Did the Name Calico Come From?

A fabric of cotton cloth, the name being derived from the city of Calicut, in Madras, where it was first manufactured, and in 1631 brought to England by the East India Company. Calico-printing, an ancient Indian and Chinese art, has become a great industry in this country and in Britain, as well as in Holland.

Who Made the First Postage Stamp?

The stick on postage stamps so generally used today was invented by an Englishman James Chalmers in 1834. The English Government passed a bill calling for uniform postage of One Penny in 1840 and furnished envelopes bearing stamps printed on them. The people did not like them, however, and the adhesive stamp invented by Chalmers was substituted. The first stamps used in America were introduced in 1847. People have, it seems, always preferred to lick their postage stamps.

How Many Languages Are There?

It is said that there are more than 3,400 languages, including dialects, in the world. Most of them belong, of course, to savage or uncivilized people. There are said to be more than 900 languages used in Asia, almost 600 in Europe, 275 in Africa and more than 1,600 languages and dialects which are American.

What Is the Deepest Mine In the World?

The mine that goes farther down than any other in the world is the rock salt mine near Berlin, Germany which is 4,175 feet. It is not, however, straight down but somewhat slanting. The Calumet Copper Mine near Lake Superior is at a depth in some places of 3,900 feet.

The deepest boring in the world is an artesian well at Potsdam, Missouri, which is 5,500 feet deep or more than one mile straight down.

What Is Color?

~WHAT PRODUCES THE COLORS WE SEE?~

What is termed the color-sense is the power or ability to distinguish kinds or varieties of light and their distinctive tints. We owe the faculty of doing this to the structure of the eye and its elaborate connecting nerve machinery. The eye in man is specially sensitive to light, and the sensations we feel through it enables us to distinguish the different colors. Over 1,000 monochromatic tints are said to be distinguishable by the retina of the eye, though these numerous tints are, in the main, merely blendings or combinations of the three primary color-sensations, the sense of red, of green and of violet. Each of these colors, it has been demonstrated, is produced by light of a varying wave length, while white light is only light in which the primary colors are combined in proper proportion. Colored light, on the other hand, as Newton proved, may be produced from white light in one of three ways: First, by refraction in a prism or lens, as observed in the rainbow; second, by diffraction, as in the blue color of the sky, or in the tints seen in mother-of-pearl; and third, by absorption, as in the red color of a brick wall, or in the green of grass--the white light which falls upon the wall being wholly absorbed, save by the red, and all that falls upon the grass being absorbed except the green. In art, color means that combination or modification of tints which is specially suited to produce a particular or desired effect in painting; in music, the term denotes a particular interpretation which illustrates the physical analogy between sound and color.

Where Did the Term Dixie Originate?

The term was applied originally to New York City when slavery existed there. According to a myth or legend, a person named Dixie owned a tract of land on Manhattan Island and had a large number of slaves. As Dixie's slaves increased beyond the requirements of the plantation, many were sent to distant parts. Naturally the deported negroes looked upon their early home as a place of real and abiding happiness, as did those from the "Ole Virginny" of later days. Hence "Dixie" became the synonym for a locality where the negroes were happy and contented. In the South, Dixie is taken to mean the Southern States. There the word is supposed to have been derived from Mason and Dixon's line, formerly dividing the free states from the slave states. It is said to have first come into use there when Texas joined the Union, and the negroes sang of it as Dixie. It has been the theme of several popular songs, notably that of Albert Pike, "Southrons, Hear Your Country Call"; that of T. M. Cooley, "Away Down South where Grows the Cotton," and that of Dan Emmett, the refrain usually containing the word "Dixie" or the words "Dixie's Land." During the Civil War, the tune of "Dixie" was to the Southern people what "Yankee Doodle" had always been to the people of the whole Union and what it continued, in war times, to be to the Northern people, the comic national air. The tune is "catchy" to the popular ear and it was played by the bands in the Union army during the war as freely as by those on the other side. During the rejoicing in Washington over the surrender of Lee at Appomattox, a band played "Dixie" in front of the White House. President Lincoln began a short speech, immediately afterward, with the remark, "That tune fairly belongs to us now; we've captured it."

How Big Is the Earth?

The third planet in order of distance from the sun, Mercury and Venus being nearer to it. It is in shape a sphere slightly flattened at the poles and bulged at the equator, hence it is called an oblate spheroid. The equatorial diameter or axis measures 7,926 miles and 1.041 yds., and the polar diameter is 7,899 miles and 1.023 yds. The earth revolves upon its axis, completing its diurnal or daily revolution in a sidereal day, which is 3 minutes and 55.9 seconds shorter than a mean solar day. It revolves around the sun in one

sidereal year, which is 365 days, 6 hours, 9 minutes, and 9 seconds. Its orbit or path around the sun is an ellipse, having the sun in one of the foci. The earth's mean distance from the sun is 93,000,000 miles. Its axis is inclined to the plane of its orbit at an angle of 23° 27′ 12.68″. The circumference at the equator measures 24,899 miles. The total surface is 196,900,278 sq. miles, and the solid contents is 260,000,000,000 cubic miles. As we descend into the earth the temperature rises at the rate of 1° Fahr. for every 50 ft. At the depth of 10 or 12 miles the earth is red-hot, and at a depth of 100 miles the temperature is such that at the surface of the earth it would liquefy all solid matter in the earth.

What Causes Hail?

Hail is the name given to the small masses of ice which fall in showers, and which are called hailstones. When a hailstone is examined it is found usually to consist of a central nucleus of compact snow, surrounded by successive layers of ice and snow. Hail falls chiefly in Spring and Summer, and often accompanies a thunderstorm. Hailstones are formed by the gradual rise and fall, through different degrees of temperature (by the action of windstorms), and they then take on a covering of ice or frozen snow, according as they are carried through a region of rain or snow.

With regard to rain, it may be said, in popular language, that under the influence of solar heat, water is constantly rising into the air by evaporation from the surface of the sea, lakes, rivers, and the moist surface of the ground. Of the vapors thus formed the greater part is returned to the earth as rain. The moisture, originally invisible, first makes its appearance as cloud, mist or fog; and under certain atmospheric conditions the condensation proceeds still further until the moisture falls to the earth as rain. Simply and briefly, then, rain is caused by the cooling of the air charged with moisture.

Why Does a Human Being Have To Learn to Swim?

It is strange, isn't it, that almost every animal, excepting man and possibly the monkey, knows how to swim naturally; others such as birds, horses, dogs, cows, elephants, can swim as soon as they can move about alone.

The trouble with man in this connection is that his natural motion is climbing. He has been a climber ever since he was developed from the monkey, and when you throw him into the water before he has learned to swim, he naturally starts to climb and as a climbing motion won't do, for swimming, the man will drown.

This climbing motion is as much of an instinct in man and monkeys as the instinct in dogs which causes him to turn round once or twice before he lies down just as his forefathers used to do ages ago when, as wild dogs, they first had to trample the grass before they could lie down comfortably.

Why Do I Get Cold in a Warm Room?

I suppose you mean the instances when you get cold while in a warm room even when you are perfectly well. This will happen often when all of the moisture in the room outside of what is in your body, is evaporated by the heat in the room. The remedy is, of course, to keep a pan of water some place in the room as the air has become too dry.

While heat is necessary to evaporate water, the process of evaporation produces cold. The quicker the evaporation the sharper the cold feeling produced. Now your body is continually evaporating the water from your body which comes out in the form of perspiration through the pores of the skin. This is one of nature's ways of taking the impurities and waste out of the body. You know, of course, don't you, that more than one-half the waste material which the body expels from the system comes out through the pores of the skin rather than through the canals.

When the air in the room becomes too dry, the evaporation on the outside of the body proceeds faster and makes you cold. By keeping water in some vessel in the room you keep the air of the room from becoming too dry.

Why Do They Call Them Wisdom Teeth?

The wisdom teeth are the two last molar teeth to grow. They come one on each side of the jaw and arrive somewhere between the ages of twenty and twenty-five years. The name is given them because it is supposed that when a person has developed physically and mentally to the point where he has secured these last two teeth he has also arrived at the age of discretion. It does not

necessarily mean that one who has cut his wisdom teeth is wise, but that having lived long enough to grow these, which complete the full set of teeth, the person has passed sufficient actual years that, if he has done what he should to fit himself for life, he should have come by that time at the age of discretion or wisdom. As a matter of fact these teeth grow at about the same age in people whether they are wise or not.

What Makes Freckles Come?

Freckles are generally caused by the exposure of unprotected parts of the body to the sun, but this will not cause freckles on all people. Only people with certain kinds of sensitive skins freckle. What happens when freckles are produced in this way is this: The sunlight shining on the face, neck or arms of anyone who has a tendency to freckle, has a peculiar action on certain cells of the skin which produces a yellowish brown coloring pigment, which remains for a time.

Then again the skins of some people are so peculiarly sensitive the cells develop this kind of coloring matter in almost any kind of light and such people are, so to speak, apt to be freckled for life.

The Flying Boat

When Did Man First Try to Fly?

~HOW MAN LEARNED TO FLY~

Man’s desire to conquer the air is older than recorded history. When a kite was flown for the first time the principle of aviation, or dynamic flight, was uncovered. For centuries man has sought the mechanical equivalents for the things that keep a kite flying steadily in the air,--the power that lies in the cord that keeps a kite headed into the wind; an equivalent for the wind’s own power; an equivalent for the tail which controls the kite’s lateral and longitudinal balance.

Each separate part of the modern flying machine, or aeroplane, was worked out long ago, with the exception of the gas engine light enough and reliable enough to be used for this work. The present generation knows dynamic flight as a commonplace thing, not because we are so much more clever than previous generations in designing flying machines, but because of the development of the modern gasoline or internal combustion engine.

Who Invented Flying?

No one invented flying, nor did any one man invent all the separate parts of the flying machine. They are the result of evolution,--of the combined work and thought of hundreds of men, many of whose names are unrecorded. To attempt to find the true beginning of the modern flying machine would be as difficult as attempting to discover who planted the seed of the tree from which one has gathered a rose. But the tree from which all the flying machines, or aeroplanes, of today have sprung undoubtedly is Dr. Samuel Pierpont Langley, third secretary of the Smithsonian Institution.

Some of the Men Who Helped.

Taking the most conspicuous names of scientists who worked out various details of the aeroplane during the past century we find that a century ago Sir George Cayley built a machine on lines very similar to those accepted today, and he went so far as to foretell the necessity of developing the internal combustion engine before dynamic flight could be a success. Mr. F. H. Wenham, in 1866, also built a flying machine along conventional lines and tried to fly it with a steam engine, which of course, proved too heavy.

[Illustration: One of Dr. Langley’s first models; a biplane with flexible wing-tips and twin propellers. 1889.]

~EARLY TYPES OF FLYING MACHINES~

M. A. Penaud, a Frenchman, in experimenting with models, seems to have been the first to discover the necessity of vertical and horizontal rudders in maintaining balance. Mr. Horatio Phillips, an Englishman, discovered, and patented, the use of curved instead of flat surfaces for the planes. Otto and Gustav Lilienthal are said to have been the first to attempt to balance aeroplanes by flexing or bending the wings. Various others, including Messrs. Richard Harte, Boulton, Mouillard, worked out ideas for balancing

machines by the use of auxiliary planes which could be set at different angles with regard to the line of flight, thus forcing the machines to different positions by the force of the air rushing against them.

Dr. Langley, trained in scientific investigation, conducted an elaborate series of experiments covering many years and costing thousands of dollars to test and prove the value of the claims of the earlier investigators. Some things which he thought he was the first to discover,--such as the effect of the vertical and horizontal rudders,--he later found had already been proven by others. Independently he covered the entire field of experiment and after building hundreds of small models he succeeded, in 1896, in making a machine weighing several pounds equipped with a very light steam engine which flew safely as long as the fuel lasted. For his early experiments Dr. Langley was afforded financial assistance by Mr. William Thaw of Pittsburg. After the success of his small machines Dr. Langley was asked to undertake the construction of a large, man-carrying machine, and Congress voted him $50,000 to carry on the work. A large share of this was spent on the development of a very light gasoline engine. The machine finally was completed, but was twice broken through defective launching apparatus. Congress and Dr. Langley were so ridiculed by the public press that the machine was temporarily abandoned. Not, however, until after Dr. Langley had successfully flown a steam driven machine much larger than many of the racing aeroplanes of today.

But eight years after Dr. Langley's death, which is said to have been due to the heart-breaking disappointment he suffered in trying to demonstrate the large machine, Glenn H. Curtiss, at the request of the Smithsonian Institution, rebuilt the old Langley machine and succeeded in making a flight with it at Hammondsport, N. Y., on May 28, 1914.

[Illustration: THE FIRST MAN-CARRYING AEROPLANE

First successful man-carrying aeroplane. Designed by Dr. Langley in 1898; flown by Glenn H. Curtiss at Hammondsport, N. Y., 1914.]

[Illustration: Front view of big Langley machine in 1914.]

While longer flights probably will be made with this machine none will attain greater importance, because this first flight with it was sufficient to establish for all time the fact that Dr. Langley built the first man-carrying machine equipped with a gasoline engine and able to fly and raise itself with its own power. This was considerably more than was accomplished by other machines for some time after Dr. Langley's death. The Langley machine not only lifted the weight it was designed to fly with, but also carried pontoon and other fittings, added by Mr. Curtiss to make flight from the water possible, which added 340 pounds to the original weight of the machine.

[Illustration: THE MACHINE WITH WHICH BLERIOT FLEW IN EUROPE

Copy of early Langley model with which Bleriot made first circular flight in Europe.]

The connection between Dr. Langley's work and present machines is now very easy to trace, though not obvious until 1911, when the Smithsonian Institution published memoirs written by Dr. Langley in 1897, and some memoirs of Mr. Octave Chanute, a French engineer who resided in Chicago, and who forms one of the main connecting links. The chain is practically completed by notes left by the late Lieut. Thomas Selfridge, U. S. A., America's first martyr to aviation.

Dr. Langley's knowledge is represented in modern aviation by three distinct lines. The central and most direct line is through Dr. Alexander Graham Bell, inventor of the telephone, to the Aerial Experiment Association, and thence to Mr. Glenn H. Curtiss, and finds its expression in what is known as the Curtiss type of machines.

Another line is that carried by a Mr. A. M. Herring to Mr. Chanute and by him transmitted to Mr. Wilbur Wright, finding expression in the Wright type of biplane.

The third line is that leading to the modern monoplane school; M. Bleriot having first copied in toto the tandem monoplane form, generally known as the Langley type, and later, with the development of better gasoline engines, developing into the monoplane as known today.

With the exception of M. Bleriot it is doubtful if the others fully realized the source of their inspiration,--not to call it information.

Dr. Bell was interested in Dr. Langley's work for more than ten years before Dr. Langley gave up. He observed many of the trials, and his reports of the first successful flights are incorporated in the official publications of the Smithsonian Institution. Dr. Bell began some independent experiments, but following Dr. Langley's death he formed the Aerial Experiment Association, to carry on the

work left by Dr. Langley. The members of this organization were, Mr. Curtiss, at that time the most successful builder of light motors; Lieut. Thomas H. Selfridge, U. S. A.; Mr. J. A. D. McCurdy and Mr. F. W. Baldwin, two young Canadian engineers. Mrs. Bell financed the project, furnishing the sum of $35,000 for the experiments.

~WHAT TWO BROTHERS ACCOMPLISHED FOR FLYING~

The Wright Brothers, for Wilbur Wright was joined by his brother Orville in the experiments, were the first to reap success from the seeds of Dr. Langley's sowing. Mr. Chanute had been experimenting with a biplane form of motorless glider with little success, because of lack of means for balancing the machines in the air, until he was joined by a former employe of Dr. Langley. He appears to have imparted to Mr. Chanute the secret of the stabilizing effect of the Penaud tail, or combination of vertical and horizontal rudders. Thereafter hundreds of successful gliding flights were made with the Chanute biplane, though Chanute seems not to have grasped the full significance of the rudders,--though it was well understood by Dr. Langley. To the Chanute machine, as described to him, Mr. Wright added first the idea of flexing or warping the wings, after the fashion set by the Lilienthals. He found, however, as Dr. Langley had found years before, that in attempting to correct lateral balance in this way caused the aeroplane to swerve to such an extent that the fixed vertical rudder, as originally employed, did not correct the upsetting tendency that was developed. Mr. Wright then arranged his rudder in such a way that when the wing was warped the rudder turned in a way to offset the swerve. This combination was patented all over the world and has resulted in much complicated litigation.

To this machine the Wright Brothers added a gasoline motor in December, 1903, and with it made numerous flights during 1904-5. Their claims were not generally credited however until a later date for their experiments had been conducted with considerable secrecy, and during 1906, 1907 and until late in 1908 they did no more flying.

In the meantime M. Bleriot had made a copy of one of the early Langley tandem monoplane models and made some fairly successful flights with it in Europe. Later, as gasoline motors developed in power for weight, he reduced the rear surface until the modern monoplane evolved.

While Bleriot was working in Europe, Dr. Bell's Aerial Experiment Association in America was evolving still another type of machine, and the members of the association made the first successful public flights in America. Mr. Curtiss won the Scientific American Trophy for the first time on July 4th, 1908, by a straightaway flight of more than a kilometer. The balancing system employed by the A. E. A. differed from that employed by the Wrights and by Bleriot in that small auxiliary planes took the place of warping planes for righting the machine. This they claimed to be a superior method, first, because it eliminated the use of the rudder as being absolutely essential to the balance of the machine; second, because it enabled them to make the main planes rigid throughout, and consequently stronger than the flexible planes.

There are several other names that must be mentioned in connection with the early history of successful flight; these are the Frenchmen, Messrs. Henri Farman, Maurice Farman, the brothers Voisin, and Santos Dumont. These produced some of the first notably successful aeroplanes in Europe but seem to have discovered nothing which has had any marked effect upon the later development of flying machines. M. Farman adopted the auxiliary planes used by the A. E. A. and modified them to suit his ideas.

~WONDERFUL RECORDS OF AEROPLANES~

Volumes could be, in fact, have been written about the exploits of the first demonstrators of the practical heavier-than-air flying machines,--of the crossing of the English Channel by Bleriot, of the flights by Wilbur Wright at Rheims, France; of Mr. Curtiss' winning of the first Gordon Bennet International speed trophy and his flight down the Hudson from Albany to New York; of Orville Wright's flight at Fort Meyer, and the death of Lieut. Selfridge who was flying with him. The barest record of these interesting accomplishments would fill volumes. Of the aeroplane proper it is enough to say here that since 1908 its development has been too rapid for accurate recording. In strength, in speed, in reliability, in size and carrying capacity, it has developed at a remarkable rate. At this writing the speed record is about 130 miles per hour; the duration record is more than 24 hours, non-stop; the distance record is some 1,300 miles in one day; the altitude record some 26,000 feet. New records succeed the old ones with such rapidity that probably before this can be printed all these present records will have been greatly eclipsed.

[Illustration:

AEROPLANE "RED WING" HAMMONDSPORT, N.Y.

FIRST AMERICAN PUBLIC FLIGHT, MAR 12 1908]

[Illustration: The biplane in which G. H. Curtiss flew from Albany to New York in 1910.]

Meantime the aeroplane has developed greatly in other directions. In flying over land with the early types of machines many fatal accidents occurred, particularly to the fliers who gave exhibitions everywhere during 1909, 1910 and 1911. A majority of these accidents were indirectly due to the fact that a very smooth surface is required for landing a fragile machine running at high speed. The obvious expedient was to develop machines capable of rising from and alighting upon the water.

[Illustration: SOME FAMOUS FOREIGN MONOPLANES

A modern German monoplane.]

[Illustration: The machine in which Bleriot crossed the English Channel in 1909. A modified Langley type.]

[Illustration: Rolland Garros and monoplane in which he flew across the Mediterranean Sea in 1914.]

~THE WONDERFUL FLYING BOAT~

During the winter of 1910 and 1911 Mr. Curtiss, who had continued independent experiments upon the disbandment of the Aerial Experiment Association, succeeded in producing the first machine to safely leave and return to the water. For the development and demonstration of this type of flying machine he was awarded the Aero Club of America Trophy, and when during 1912 he produced still another type of water flying machine, the Curtiss Flying Boat, he was again awarded the Aero Club Trophy and also voted a Langley Medal by the directors of the Smithsonian Institution.

[Illustration: Different views of flying boat.]

Not until the development of the flying boat did the general public begin to take a participative interest in aviation, but as soon as the comparative safety of this type of machine became apparent the new sport began to be taken up rapidly both in this country and in Europe. The experiences of naval fliers and amateurs alike went to show that water flying offered not only the fastest and most comfortable mode of rapid travel, but also the safest, for during 1913 several hundred thousand miles were flown by navy aviators and amateur enthusiasts in Curtiss water flying machines without a single serious accident.

What aviation will mean to future generations,--even to this generation in the course of a few years,--it would be foolhardy to try to guess. Mr. Rodman Wanamaker already has agreed to furnish the financial support for Mr. Curtiss' attempt to build a machine to fly across the Atlantic Ocean, from America to Europe. If the venture is successful it is expected the crossing will be made in a fraction of the time taken by the fastest Transatlantic liners. The discovery of new metals and new manufacturing methods will certainly result in the development of light motors that may be relied upon to run for days without stopping, and automatically stable aeroplanes seem to be not far away. This will result in overland flight as safe and sure as we now enjoy over water.

~GREATEST PRESENT VALUE OF AEROPLANE~

At present the greatest value of the aeroplane seems to be for military reconnaissance and all the great powers are striving their utmost to secure supremacy in the air. France, Germany, Russia and England have to date spent millions in developing aeroplane fleets. Only the government of the United States has failed as yet to appreciate the military significance of the flying machine. If the relative aeronautical strength of the world's nations were represented alphabetically the U. S. would naturally scarce have to change its initial, U being slightly in advance of Z which would stand for Zululand. But even with its modest equipment the navy fliers of the United States proved the great worth of the aeroplane and the flying boat, when during the recent trouble in Mexico the

air scouts gathered in a few minutes information that could only have been secured by days of cavalry scouting before the advent of the flying machine. Indeed, the name of Lieut. P. N. L. Bellinger, the most able of the naval fliers at Vera Cruz, has figured more prominently in the despatches from the front than that of any other officer connected with the expedition.

Flying seems certain in the very near future to take its place as the fastest, safest and most comfortable mode of conveyance. The flying boat will render quickly accessible the vast country lying along the great rivers of South America, Africa, and Australia; it will bridge the great lakes and the oceans; bring near together the islands of the Pacific and Indian oceans. It will make imperative, because of the speed with which distances will be traversed, of a language common to all peoples; and treble man's life without extending his years by making it possible to see and do three times as much in the same length of time.

~TEN YEARS OF FLYING~

Ten years ago on that day, December 17, 1913, Wilbur and Orville Wright made four flights on the coast of North Carolina near Roanoke Island, a spot historic in America's history as the site of the first English settlement in the Western Hemisphere.

[Illustration: Flying over military post in Curtiss biplane.]

The first flight started from level ground against a 27-mile wind. After a run of 40 feet on a monorail track, the machine lifted and covered a distance of 120 feet over the ground in 12 seconds. It had a speed through the air of a little over 45 feet per second, and the flight, if made in calm air, would have covered a distance of over 540 feet.

Altogether four flights were made on the 17th. The first and third by Orville Wright, the second and fourth by Wilbur Wright. The last flight was the longest, covering a distance of 852 feet over the ground in 59 seconds. After the fourth flight, a gust of wind struck the machine standing on the ground and rolled it over, injuring it to an extent that made further flights with it impossible for that year.

1903]

The gliding experiments of Lilienthal in 1896 led the Wright Brothers to become interested in flight. The next four years were spent in reading and theorizing. In the Fall of 1900 practical experiments were begun with a man-carrying glider. These experiments were carried on from the sand hills near Kitty Hawk, North Carolina. The first glider was without a tail, the lateral equilibrium and the right and left steering were obtained by warping of the main surfaces. A flexible forward elevator was used. This machine was flown as a kite with and without operator, and several glides were made with it.

A second machine was designed of larger size, and many glides were made with it in 1901. This machine was similar to the one of 1900 but had slightly deeper curved surfaces. Experiments with this machine demonstrated the inaccuracy of all the recognized tables of air pressures, upon which its design had been based.

In 1902 a third glider was constructed, based upon tables of air pressures made by the Wright Brothers themselves. The lateral control was maintained by warping surfaces, and a vertical rear rudder operated in conjunction with the surfaces. Nearly a thousand gliding flights were made with this machine.

In 1903, the Wright Brothers designed a machine to be driven with a motor. They also designed and built their own motor. This had four horizontal cylinders, 4 in. by 4 in., and developed 12 h.p. Two propellers, turning in opposite directions, were driven by chains from the engine. After many delays the machine was finally ready and was flown on the 17th of December, 1903, as related above.

In the Spring of 1904, power flights were continued near Dayton with a machine similar to the one flown in 1903, but slightly heavier.

The first complete circle was accomplished on the 20th of September, 1904, in a flight covering a distance of about one mile. Altogether 105 flights were attempted during the year, the longest of which were two of five minutes each, covering a distance of

about three miles. All of the flights were started from a monorail.

After September a derrick and a falling weight were used to assist in launching the machine.

~INTERESTING GOVERNMENTS IN FLYING MACHINES~

It was not till 1908 that the Wright Brothers found purchasers for their invention. In that year they made a contract to furnish one machine to the Signal Corps of the United States Army and to sell the rights to their invention in France to a French company. In both cases they agreed to carry a passenger in addition to the operator, fuel sufficient for a flight of 100 miles, and to make a speed of 40 miles an hour.

After making some preliminary practice flights at their old experiment grounds near Kitty Hawk in May, 1908, Wilbur Wright went to France to give demonstrations before the French Syndicate and Orville Wright to Washington to deliver the machine to the United States Signal Corps. The machines used by Wilbur Wright had been standing in bond in the warehouse at Havre since August of the year before. Owing to damage done to the machine in shipment, it was not ready for the official demonstrations until late in the year.

Meanwhile Orville Wright in September, 1908, started demonstrations of the machine contracted for by the United States Government. On the 9th he made two flights, one of 57 minutes, and the other one hour and 2 minutes, world's records. On the 10th and 11th, these records were increased and on the 12th a flight of 1 hour and 15 minutes was made. On the 17th, the tests were terminated by an accident in which Lieutenant Selfridge met his death and Mr. Wright was severely injured, so that he was not able to complete the tests until the following year.

Four days after the accident, on the 21st of September, Wilbur Wright made a flight of 1 hour and 31 minutes at Le Mans, France, which record he improved several times during the following months, and on the 31st of December, won the Michelin Trophy by a flight, in which he remained in the air 2 hours and 24 minutes.

Where Is the Wind When It Is Not Blowing?

The answer is, of course, that there isn't any wind then. To understand this perfectly we must study a little and find out what wind is. In plain words it is nothing more than moving air.

If you make a hole in the bottom of a pail of water the water will run out slowly. If you knock the whole bottom out of the pail filled with water, the water will rush out before you know it.

That is about what happens to make the wind. The air is constantly full of air currents, like the currents you can see in a river. Down the middle of the river you may notice a softly-flowing current going straight. Along the shores there will be little side currents going in all directions, and you may find some little whirlpools. That is exactly what we should see in the air if we could see air currents.

Where Does the Wind Begin?

The movement of these currents of air leaves many pockets of space where there is no air, and when one of these is uncovered the air rushes in and creates a wind in doing so. These air currents are continually pressing against each other to get some place else. They change their direction according to the pressure that is being applied to them. Sometimes the pressure will be very light in one part of the air, many miles away perhaps, and then the air in another part, which is under great pressure, will rush with great force into the part where the pressure is light, and thus form a big wind. When the pressure stops the wind stops.

We have probably felt the wind which comes out of the valve of the automobile tire when the cap is taken off to pump up the tire. It is a real wind that comes out. The reason is that the air in the tube of the tire is under great pressure, and when the opportunity is given to get where the pressure is light it starts for that place with a rush and comes out of the valve a real wind.

What Causes the Wind's Whistle?

The whistle of the wind is caused very much like the whistle you make with your mouth or the noise made by the steam escaping through the spout of the kettle. You do not hear the wind whistle when you are out in it. You can hear it when you are in the house and the wind is blowing hard. When the wind blows against the house it tries to get in through all the crevices, under the cracks of the doors, down the chimneys, wherever it finds an opening. And whenever it starts through an opening that is too small for it, it makes a noise like the steam coming out of the spout of the kettle, provided the opening is of a certain shape.

Not all the noises made by the wind, however, are made in this way. The wind in blowing against things makes them vibrate like the strings of a piano or violin, and when things vibrate, as we have already seen, they produce sound waves, which, when they strike our ears, produce sounds of various kinds. The wind even on ordinary days makes the telegraph and telephone wires hum, as you can prove to yourself by placing your ear against a telegraph or telephone pole, and whenever the wind makes anything vibrate, a great many queer sounds are produced, which often frighten us more than they should.

Why Does the Air Never Get Used Up?

Simply because it is constantly being replenished. The three gases, oxygen, nitrogen and carbonic acid gas, which are found in the air about us, are constantly being used up. All living animal creatures are at all times taking oxygen out of the air to live on. Certain microbes are using up quantities of the nitrogen all the time, and the plants live on the carbonic acid gas. But while these different kinds of life between them use up the air, they give back something also. The plants give off oxygen. The bodies of the animals and plants when they die decompose, and as they are full of nitrogen, that is given back to the air in that way, and then all living creatures are always throwing off carbonic acid gas through their lungs, and thus everything that is taken out of the air is put back again. The plants live on carbonic acid gas, and give us back oxygen. The living creatures live on oxygen and give off carbonic acid gas, and when they die their bodies put back in the air the nitrogen which the microbes take out, and so, consumption and production are about equal all the time.

Why Can't We See Air?

We cannot see air because it has no color and is perfectly transparent. If at times it appears that there is color in the air it is not the air you see, but some little particles of various substances in it. Sometimes you think when you look off toward a range of mountains or hills, for instance, that the air is blue. You know the grass and trees on the mountains are green, so it cannot be they that have turned blue, and so you think the air is blue. But it is only the sunlight reflected to your eyes from the little particles of dirt and other substances which fill the air at all times which makes the blue that you see, and not the air.

Pure air is a mixture of gases without any color and is perfectly transparent. Air is nearly entirely composed of a gas called nitrogen--the remainder being oxygen with a little water and carbonic acid gas, which latter is thrown off in breathing. This is, however, but a very small percentage.

Air has been and still can be reduced to a liquid state, and with the use of it in this form many seemingly wonderful things can be done, which are interesting to look at, but have not as yet become commercially practical.

Why Does Thunder Always Come After the Lightning?

This occurs simply because lightning or light travels so much more quickly than sound. Light travels at the rate of 186,000 miles per second, and sound travels only at the rate of 1090 feet per second when the temperature is at 32 degrees. Now, the thunder and lightning come at the same time and place in the air, but the light travels so much faster that you see the lightning often quite some seconds before you hear the thunder. In fact, you can tell quite accurately how far away from you the flash of lightning and clap of thunder are by taking a watch and noting the number of seconds which elapse between the flash of the lightning and the time when you hear the roll of the thunder. If as much as five seconds elapse you can figure that it was about a mile away from you, since sound travels only about 1100 feet per second and there are 5280 feet in a mile. When the thunder and lightning come close

together you may know that it is near by, and when they come at the same time you may be sure it is very close. When, therefore, you see the lightning and then have to wait several seconds for the noise of the thunder, you may rest easy about the lightning hurting you, because you know then it is too far away to harm you, and when it is so close that the lightning and thunder come simultaneously, there is no use being afraid, because if you were to be struck you would have been struck at the same instant or before you would have had time to notice that the lightning and thunder come together.

How Big Is the Sun?

It is very difficult to gain a clear idea of how very large the sun really is. We know from the scientists who have measured it with their accurate measuring instruments that it is 865,000 miles through it, and that at its largest part it is 2,722,000 miles around. Now, you can see why I said it is very difficult to get a clear conception of the sun's size. A mile is quite a long distance to walk on a hot day. Now, the earth is 8000 miles through. If there were a tunnel right through the earth, like the subway, and you started to walk it, it would take you 83½■ days if you walked day and night without stopping to rest or eat, if you kept going at the rate of four miles every hour. This would be a long, hot walk, for, of course, the inside of the earth is hot, as we have already learned. It would take an automobile, going at the rate of 40 miles an hour night and day, about nine days to make the trip through such a subway from one side of the earth to the other. That makes it look like a pretty big old earth, doesn't it? But let us see what would happen if we started to do the same thing on the sun. The sun is 865,000 miles through. If you were to walk through a similar tunnel on the sun at four miles per hour it would take you 20 years, not counting the stops, and an automobile going 40 miles an hour day and night would take two years and a half to make the trip one way.

The sun is ninety million miles from the earth and an automobile travelling at the rate of forty miles per hour day and night on a straight road, without stopping, would be 257 years in getting there.

When we stop to think of how big the bulk of the sun is it is altogether beyond us. We have a general idea that our earth is a pretty large affair as worlds go, and yet we cannot conceive how much the bulk of the earth amounts to. Still, the sun is so large that it could contain a million worlds like our own.

How Hot Is the Sun?

We think the sun is pretty hot in summer when the thermometer goes up to 90 degrees in the shade or out. We begin to get sunburned long before it reaches that high. But right on the sun's surface it is between 10,000 and 15,000 degrees hot. That is, of course, a degree of heat which we cannot conceive. How much hotter still it is on the inside of the sun we don't as yet know. It must be awfully hot there.

Why Is It Warm in Summer?

It is warm in summer because at that season of the year the heat rays of the sun strike our part of the earth through less air. The blanket of air which surrounds the earth is very much in comparison as to thickness like the peeling of an orange and surrounds the earth in just the same way. If you stick a pin straight into an unpeeled orange you only have to stick it in a little way before you reach the juicy part of the orange, but if you stick the pin in at an angle the pin will travel a much longer ways through pure peeling before it strikes the juicy part. Now, then, in summer the rays of the sun come down to us straight through the peeling of air, and less of the heat is lost by contact with the air, and that makes it warmer in summer. The explanation also accounts for your next question.

Why Is It Cold in Winter?

In winter the heat rays of the sun strike at our part of the earth at the angle at which you stick the pin into the orange when you wish to make it travel through the most peeling. In winter the rays strike the earth at such an angle that a great deal of the heat is lost in travelling through the air, because they have to come through so much more of the air. Of course, the sun's rays strike some part of the earth straight down through the peeling of air at all times, and at the equator this occurs all the year round, so it is always summer there, while at the North and South Poles the rays always strike the earth at the greatest possible angle, and it is always very cold winter there. In between, when it is neither hot nor cold, we have spring and fall, due to the fact that the rays come down at an angle, but not so great an angle.

Why Have We Five Fingers on Each Hand and Five Toes on Each Foot?

All animals, it seems, from a study of nature were started with ten fingers and ten toes, the fingers originally having been the toes of the fore legs. In a good many cases the environment in which animals have lived has caused a change in the formation of the ends of the limbs as well as in the limbs themselves. The horse, for instance, has developed into a one toe or one finger animal, while a cow is a two finger animal. The hen has only three toes on each foot and a part of another. But if we go back into the history and examine how the horses' foot used to look we will find that he originally had five toes. The same is true of the cow and also the hen. Something happened to cause the change, for the rule of five fingers and five toes on the end of each limb has been universal. If you examine a chicken in a shell just before it is ready to come out, you can distinctly count five toes on each foot and at the ends of the wings you will see five little points, which under other conditions would develop into fingers, perhaps. Some of these toes of the new-born chicken do not develop. It can be accepted as a rule that creatures were intended in the original plan to have five fingers on each hand and five toes on each foot, making our count of tens, which is the world's basis for counting, and has always been.

Why Do We Have Finger Nails?

Finger nails and toe nails are only another phase of the development of man from the animal that originally walked on four feet. Animals that walk on all fours use the finger and toe coverings which in man is the nail, to scratch in the ground, to attack enemies, and to climb with, and our nails of the present day are what the development of man into a civilized being has changed them to. At that, there are still uses for finger nails and toe nails, or man in his changing to a higher plane would have found a way to develop away from them. They are useful to-day in making our fingers and toes firm at the end, and enable us to pick up things more easily. The time may come when man will have neither finger nails nor toe nails.

Why Are Our Fingers of Different Lengths?

There is no known reason why our fingers should be of different lengths to-day; in fact, it is thought by some people that the hand would be stronger if the fingers were all of the same length. Certainly, however, the hands would not then be so beautiful, and it might not be so useful. The human hand to-day is perhaps the most versatile thing in the world. You can do more things with the hand than with any other thing in the world. The probability is that the shape of the hand to-day and the length of the fingers are the result of the different things the human being has called upon the hand to do during man's development up to the present time.

We must go back to the time, however, when man walked on fours, for that is probably the real explanation. Originally man's fingers were of different lengths because all four-footed animals had the same peculiarities. The shape and length of the toes and their arrangement were the ideal arrangement for giving the proper balance and support to the body, and in moving about and in climbing produced the best toe hold.

Why Does It Hurt When I Cut My Finger?

It hurts when you cut your finger, or, rather, where you cut it, because the place you have cut is exposed to the oxygen in the air, and as soon as it is so exposed a chemical action begins to take place, just as when you cut an apple and lay it aside you come back and find the cut surface all turned brown. If the apple could feel it would hurt also, because the chemical action is much the same. The apple has a skin which protects its inside from the oxygen in the air, and you have also a skin which protects you from the oxygen as long as it is unbroken.

What happens, of course, is this: When you cut your finger you sever the tiny little veins and nerves which are in your finger. They are spread all over your body like a net-work under the skin, close to the surface in most places. The nerves when cut send a quick message to the brain, with which they are connected, telling that they are damaged, and the brain calls on the heart and other functions to get busy and repair the damage along the line. There may be some hurt while this process of repairing is going on, but the principal part of your hurt, outside of what we call your feelings, is due to the fact that the inside of you is thus exposed to the chemical action of the air. Then I can hear you say next:

Why Don't My Hair Hurt When It Is Being Cut?

It does not hurt to cut anything that has no nerves. There are no nerves in the hair which the barber cuts. If he pulls out a hair it hurts, because the root of the hair has nerves, which telegraph notice of the damage to the brain. When a dentist takes out or kills the nerve in your tooth you cannot have any more toothache in that tooth, because there is no nerve there to send the message to the brain. You can cut your finger nails without feeling pain, because they have no nerves at the ends, but underneath, where they join the skin of the finger, there are a great many nerves, and it hurts very much to bruise the nails at that location.

Of What Use Is My Hair?

~WHY WE HAVE HAIR~

Your hair is a relic of the days when the entire body was covered with hair, just like some animals to-day, to protect the body from the heat, cold and wet. Man has, however, for so long a time worn clothes over most of his body that the need of the hair to protect him from these elements has all but disappeared, and so also has the hair, excepting in such places as the top of the head and face and other exposed parts. If you were to go out into the woods without clothes and live a long time your body would probably again become covered with hairs. The time is coming, however, it is believed, when human beings will have no hair at all on their bodies. You have hair on your head, but if you were to wear a hat or cap all the time you would soon be bald. Hair is of no use to us to-day excepting to adorn our bodies and add to our appearance. This it seems to do to-day, probably because we are accustomed to seeing it, and will make no difference in our looks relatively if the time comes when we have no hair at all.

Why Does My Hair Stand On End When I Am Frightened?

It does this under certain conditions, because there is a little muscle down at the root of each hair that will make each hair stand up straight when this muscle pulls a certain way. It is difficult to say just how these muscles are caused to act in this way when we are frightened. We know that when thoroughly frightened our hair will sometimes stand straight up, and we know that it is this muscle at the root of each hair that makes it possible, but why it is that a big scare will make this muscle act this way we do not as yet know.

What Makes Some People Bald?

The chief cause of baldness is the lack of care of the hair. It is as necessary for the roots of the hair to have a free circulation of the blood and that the hair itself should have plenty of air as it is necessary for the brain to have a good circulation. A great many men become bald through wearing their hats most of the time. The hat pulled down tight over the head presses against the scalp and interferes with the circulation of the blood in the scalp. Then, also, many hats do not have any means of ventilation, and that keeps the pure air away from the hair. The hair then becomes sick and dies, just as flowers wilt if you keep them away from the air. You will notice that women do not become bald so easily. One reason is that even when the women wear large hats, as they often do, there is plenty of room for the air to circulate through the hair, even when the hat is on, and women's hats are not pulled down tightly on the scalp. Therefore, they do not press on the arteries and veins in the scalp and interfere with the circulation of the blood. Another reason why women do not become bald is that the hair of women has long been their "crowning glory"; a man likes to see a fine head of hair on a woman, and as women have long tried to please men in every possible way, they take better care of their hair than men do, because they like to have the men consider it beautiful.

What Makes Some Things in the Same Room Colder than Others?

The objects in a room which has been kept at a given even temperature of heat will be all the same temperature, because heat spreads from one thing to another equally.

Still, if you put your hands on various objects in such a room some of them will feel colder than others. You touch the tiling of the fireplace and that will feel cool to you. On the other hand, the upholstered furniture will feel quite warm. The piano keys feel cool, while the wood of the piano and case is warm. The difference is due to the fact that heat or cold will run through some objects more quickly than through others. It will run through the tiling on the hearth and the piano keys more quickly than through the upholstering on the furniture or the wood of the piano case. When you touch a thing with your finger you supply some of the heat of your body to the object through your finger. If the object is the tiling on the hearth or the keys of the piano the heat runs through it quickly and you get a cold impression in your finger. On the other hand, if you touch the upholstery on the furniture, through which the heat runs slowly, you get a warm feeling for the very same reason. Thus, anything which carries the heat away from our contact

quickly we call a cold feeling object, and if the object touched does not carry the heat away so quickly we call it a warm feeling object.

Why Does the Hair Grow After the Body Stops Growing?

The hair on our bodies is one of the things that is continually wearing or falling away, and since, like the skin, it is necessary to protect certain portions of the body, the hair keeps on growing long after the grown up period has arrived. The skin is a very necessary protection of the whole body, but is constantly being worn away, and is all the time being replaced. Your hair falls out when it is not healthy. Unless proper care is given to it, it will fall out and not grow in again, and then we become bald.

Will People All Be Bald Sometime?

There is a theory that before many years have passed human beings will lose all of the hairs which now grow on different parts of their bodies, due to the fact that we wear so much clothing and keep so much of our bodies away from the sunlight. If that time comes we shall have a hairless race of men and women.

THE STORY IN A LUMP OF SUGAR

[Illustration: PREPARING THE GROUND.--PLOWING AND HARROWING WITH A CATERPILLAR ENGINE.

Sugar beets require deep plowing, ten to fourteen inches, or twice the usual depth. When using horses, farmers are inclined not to plow deeply enough to secure maximum results, and some of the factories have put in power plows which turn six furrows and harrow the land at the same time. They plow and harrow the land of beet farmers for $2.50 per acre, which is about one-half of what it costs the farmers to plow equally deep with horses. The traction engines also are used for hauling train wagon loads of beets to the factory. In some localities farmers are banding together and purchasing engines for plowing and hauling beets. The outfit illustrated above costs about $4,500.]

[Illustration: DRILLING THE SEED.

Beets are drilled in rows, usually eighteen inches apart, 18 to 25 pounds of seed being drilled to each acre. Practically all the beet seed used in America is grown in Europe, principally in Germany, but it has been demonstrated that superior seed can be produced in the United States. Sugar-beet seed growing requires five years of the utmost skill, care and patience, from the planting of the original seed to the maturing of the commercial crop which is sold to the trade. The factories contract for their seed for three to five years in advance, sell it to farmers at cost price, and deduct the amount from the payment for beets.]

[Illustration: HOW THE BEETS ARE GROWN

BLOCKING AND THINNING.

When the beets are up and show the third leaf they should be “thinned.” Unless thinned at the proper time the pulling up of the superfluous beetlets injures the roots of the remaining ones. Scientific experiments in Germany, where all other conditions were identical, showed that one acre thinned at the proper time yielded 15 tons; the next acre, thinned a week later, yielded 13½■ tons; the third acre, thinned still a week later, yielded 10½■ tons; and the fourth acre, thinned three weeks after the first, yielded 7½■ tons.

The men in the foreground are “blocking” the beets, leaving a bunch of them every eight inches. Those in the rear are “thinning,” or pulling up the superfluous beetlets, leaving one in a place, eight inches apart.]

[Illustration: READY FOR THE HARVEST.

This field of beets yielded 20 tons to the acre. Ex-Secretary of Agriculture James Wilson is convinced that when American farmers become expert in beet culture they will average to produce more than 20 tons per acre because of the superiority of our soils. The ideal factory beet weighs about two pounds, and a perfect “stand” of such beets, one every eight inches, in rows eighteen inches apart, would yield 43½■ tons per acre. The present average yield in the United States is about 10 tons per acre, while the hitherto “worn-out soils” of Germany yield 14 tons per acre, or 40% more than is secured from our “virgin soils.”]

[Illustration: HUGE BINS TO HOLD THE BEETS AT FACTORY

TOPPING THE BEETS.

After the beets are plowed out they are topped or cut off by hand and the tops are fed to stock, for which purpose they are worth $3.00 per acre. They are topped just below the crown and the factories require that they be so topped as to remove any portion which grew above the ground, as such portion of the beet contains but a small percentage of sugar. The beet will grow in length, and, if as a result of shallow plowing or coming in contact with a rock it cannot grow downward, it will grow upward and out of the ground, thus necessitating a deeper topping and consequent loss to the farmer.]

[Illustration: DUMPING CARS AT FACTORY WITH HYDRAULIC JACK.

Beets arriving at the factory by rail from receiving stations either are stored in bins until needed or are floated directly to the beet washers. If to be used at once, they are dumped, as shown above, and slide directly into a cement flume filled with warm water, which has been pumped to its upper end, and is flowing in the direction of the beet end of the factory. In whatever manner they may be received, they first are weighed, and as they are dumped, a basket is held under them to catch a fair sample of both beets and the loose dirt, which the car or wagon contains. These samples, properly tagged, are conveyed to the beet laboratory, where they are washed, and trimmed if not properly topped, and the difference in the weight of the sample beets as received and their weight when washed is called the “tare.” Whatever percentage this amounts to is applied to and deducted from the weight of the car or wagon load. A sample of these beets then is tested by the polariscope for its sugar content and its purity; farmers often being paid a stipulated price per ton for a beet of a given sugar content and 25 to 33½■ cents per ton additional for each extra degree of sugar which they contain. The tare rooms and the beet-testing laboratories are open to any one, and in some localities the farmers’ associations employ experts to tare and analyze each sample of beets.]

[Illustration: MILLIONS OF BUSHELS OF BEETS

FACTORY BEET BINS FILLED TO CAPACITY.

As they arrive by rail from receiving stations, or by team, or traction engines from the farm, beets are stored in bins or sheds, the capacity of which ranges from 6000 to 35,000 tons per factory, depending upon location and general climatic conditions.

The bins are V shaped, about 3 feet wide at the bottom, 20 to 30 feet at the top, and they are 20 to 30 feet high. As beets are needed, beginning at one end of the bin the loose three-foot planks at the bottom are removed one at a time, and with hooks attached to long poles the beets are rolled into the flume or cement channel below, in which they are floated into the factory. This is not only to save labor, but to loosen up the dirt which attaches to the beets, thus partially washing them. The water which is used in the flumes is warm water from the factory.]

[Illustration: TYPICAL AMERICAN BEET SUGAR FACTORY.

These factories cost from half a million to three million dollars. They consume from 500 to 3,000 tons of beets per day, and during the “campaign,” which usually lasts about three months, will produce from 12 to 75 million pounds of granulated sugar. There are 73 of these factories, located in 16 States, from Ohio to California. During the operating season they give employment to from 400 to 1000 men each.]

[Illustration: WASHING THE SUGAR BEETS

CHEMICAL LABORATORY.

In a beet-sugar factory each set of apparatus for performing a given process is termed a “station.” In the chemical laboratory the juices and products from each station are tested hourly to check up the correctness of the work and to determine the losses of sugar in each process in the factory.]

[Illustration: CIRCULAR DIFFUSION BATTERY.

After being floated in from the sheds the beets are elevated from the flume to a washer, where they are given an additional washing before being sliced. From the washer they are elevated and dropped into an automatic scale of a capacity of 700 to 1500 pounds. From the scale they pass to the slicers, where with triangular knives they are cut into long, slender slices, which look something like “shoestring” potatoes. These slices drop through the upright chute seen at the right side of the picture, and are packed tightly into cylindrical vessels holding from two to six tons each; the battery consisting of eight to twelve vessels arranged either in a straight line or in circular form. Warm water is run into these slices, and coaxes out the sugar as it passes from one vessel to the

succeeding ones. After passing through the entire series of vessels the water has become rich in sugar, of which it contains from 12 to 15 per cent, depending upon the richness of the beets. It then is drawn off and is called diffusion juice or raw juice. This is carefully measured into tanks and recorded. As this juice is drawn off the vessel over which the water started is emptied of the slices from the bottom, the exhaust slices containing in the neighborhood of ½■ to ½■ per cent of sugar. These slices are carried out from the factory in the form of pulp and fed to stock, as explained later.]

[Illustration: HOW THE SUGAR IS TAKEN FROM THE BEET

CARBONATATION AND SULPHUR STATION.

Warm raw juice is drawn into the carbonatation tanks and treated with about 10 per cent milk of lime--about like ordinary whitewash. This lime throws out impurities, sterilizes the juice and removes coloring matter. Carbonic acid gas from the lime kiln is forced through the lime juice in the tank, throwing out the excess of lime, converting it into a carbonate of lime or chalk. Tests are taken here by the station operator to show when the process is finished.]

[Illustration: FILTER PRESSES.

From the carbonatation tanks the juice is pumped or forced through filter presses consisting of iron frames so covered with cloth that the juice passes through the cloth as a clear liquid, leaving the lime and impurities precipitated by it, in the frame, in the form of a cake. This cake, after washing, is dropped from the presses and conveyed out of the factory. It contains from one to two per cent of its weight in sugar, which constitutes one of the large losses of the process. It also contains organic matter, phosphate and potash, besides the carbonate of lime, which makes it an excellent fertilizer, all of which is used in Europe on the farm, but so far to too small an extent in America.]

[Illustration: EVAPORATING THE WATER FROM THE SUGAR

EVAPORATORS.

After a second, and sometimes a third carbonatation and filtration, the juice is carried to the evaporators, commonly called the “effects,” usually four (4) large air-tight vessels furnished with heating tubes running from 3000 to 7000 square feet in each vessel. A partial vacuum is maintained in these evaporators which makes the juice boil out at a low temperature, thus preventing discoloration, and to a large degree the destruction of sugar which will come about by high temperature. There always is, however, some unavoidable loss of sugar in this apparatus. The juice passes along copper pipes from first to last vessel, becoming thicker as it does so. It comes into the first vessel at 10% to 12% sugar and is pumped out of the last one so thick that it contains about 50% of sugar.]

[Illustration: VACUUM PANS.

After a careful filtration, the juice that comes from the evaporators, and is called thick juice, is pumped to large tanks high up in the building, and from these is drawn into vacuum pans. These are large cylindrical vessels from 10 to 15 feet in diameter and from 15 to 25 feet high, with conical top and bottom, built air-tight. Around the inner circumference they are furnished with 4- to 6-inch copper coils, which have a heating surface of 800 to 2000 square feet. Exhaust steam is used in the evaporators, live steam in the pans, the juice in both being boiled in a vacuum to prevent discoloration and reduce losses.

After considerable thickening by this evaporation, minute crystals begin to form. When sufficient of these have formed, fresh juice is drawn in and the crystals grow, the operator governing the size of the crystals to suit the trade. If small crystals be desired, a large quantity of juice is admitted at the outset, while if large crystals are desired, a small quantity of juice first is admitted, and, as it boils to crystals, fresh juice gradually is added to the pan, and the crystals are built up to the desired size. The operator of this pan, known as the “sugar boiler,” is one of the must important men in the factory. The water furnished the condensers of these vacuum pans and the evaporator goes to the beet sheds and is used for floating in the beets. It amounts to from 3,000,000 to 8,000,000 gallons every 24 hours, depending upon the size of the factory, and must be very pure.]

[Illustration: HOW SUGAR IS GRANULATED

FRONT VIEW OF CENTRIFUGAL MACHINES.

The mass of crystals with syrup around them and containing about 8 per cent to 10 per cent of water is let out of the vacuum pan into a large open vessel called a mixer, beneath which are the centrifugal machines. These are suspended brass drums perforated

with holes and lined with a fine screen. They are made to revolve about 1000 times to a minute, and the crystal mass of sugar rises up the side like water in a whirling bucket. The centrifugals force the syrup out through the screen holes, leaving the white crystals of sugar in a thick layer on the inner surface. These are washed with a spray of pure warm water and then are ready for the dryer.]

[Illustration: SUGAR GRANULATOR OR DRYER.

The damp white crystals from the centrifugal machine are conveyed to horizontal revolving drums about 25 feet long by 5 to 6 feet in diameter. These drums are furnished with paddles on the inside circumference, the paddles picking the sugar up and dropping it in showers as the drum revolves. Warm dry air is drawn through and takes the moisture out of the sugar, which now is ready to be put in bags or barrels for the market.]

[Illustration: BY-PRODUCTS OF THE SUGAR BEET

CRYSTALLIZERS.

The syrup that was thrown off from the crystals in the centrifugal machines is taken back to the vacuum pan, evaporated in the same manner as previously described, and from the vacuum pan goes into the crystallizers to carry the process of crystallization as far as it will go. These contain from 1000 to 1600 cubic feet of the crystallized mass which remains in them from 36 to 72 hours, during which time it is kept in constant motion by a set of slowly revolving paddles, or arms, to facilitate further crystallization. From the crystallizers it goes to the centrifugal machines, where the syrup is separated from the crystals as before. The crystals are remelted and go in with the thick juice for white sugar. The syrup, still containing a large amount of sugar, goes out to be sold as cattle feed or to an Osmose or Steffens process, where a portion of the remaining sugar may be recovered. This lost syrup constitutes the largest loss in the entire process. It contains all the impurities of the beet juice not removed by the lime. These impurities prevent more than one and one-half times their weight of sugar from crystalizing, and make what is called molasses.]

[Illustration: A SEA OF BEET PULP.

For a century the high feeding value of sugar-beet pulp has been recognized in Europe, but until a few years ago millions of tons of this valuable by-product rotted about American beet-sugar factories, as shown above, because American farmers could not be made to believe it possessed sufficient value to pay for hauling it back to the farm.]

[Illustration: MACHINE THAT FILLS, WEIGHS AND SEWS THE BAGS OF SUGAR

SACKING ROOM.--SHOWING AUTOMATIC SCALES AND SEWING MACHINE.

After the moisture has been thoroughly removed in the granulators or dryers, the sugar drops directly to the sacking room through a chute, at the lower end of which the top of the double bag is attached. The sugar flows directly into the sack, the flow being cut off automatically with each 100 pounds, when an endless belt conveyor passes the upright sack past the sewing machine at the proper speed and the product is sealed ready for storage or shipment.

While it requires from 400 to 1000 men to man a factory, not a human hand has touched either beets or product since the beets were topped in the field, and at no stage of the operation could flies or vermin or filth come in contact with the product, which from the beginning has been subjected to continuous high temperatures.]

How Can We Smell Things?

You do not need to be told what organ of the body we use in exercising the sense of smell. You can prove that easily to yourself by getting the nose within range of a distasteful smell.

We do not use all of the nose to smell with, and the nose is useful to us in other ways besides this. We use the nose a great deal in the act of respiration or breathing, and it is also useful in helping us to make sounds, form words, and, though you may not have known it, helps our sense of taste.

We smell things by means of the olfactory nerves which are located within the nose. The entire interior surface of the nose is covered with a membrane. The ends of olfactory nerves, or the nerves which give us the sensation of smell, are in this membrane, and the air, which is filled with the odor of things we smell, passes over this membrane, and thus the ends of the nerves feel the

odor and cause sensation of smell in the brain. The nerves of smell do not, however, go all through this membrane.

There are other nerves in the nose, however, besides those which give us the sensation of smell. These are also very sensitive and serve to make the nose exercise other functions when the inside of the nose is hurt or tickled. When a foreign substance, one of the many smaller particles which are constantly floating in the air, gets into the membrane in the nose, it irritates these nerves and often causes us to sneeze, which is only nature's effort to drive out this foreign substance and clean out the nose. Smell is one of the lesser of the five senses which we possess. It is one of what has been called the chemical senses. The sense of smell does not act at any great distance. This sense could be made of more value to us if we developed it. Some people have a more highly developed sense of smell than others. The lower animals have a much keener sense of smell than people. A great many of them can follow a trail for miles merely by the smell of the foot-prints, and it is said that a deer will note the presence of man or any other animal that may subject him to danger even when miles away, the odor being carried to him through the air.

How Do We Taste Things?

The sense of taste is closely associated with the sense of smell. In fact we do a good deal of what we think is tasting by using our sense of smell. A cold in the nose will sometimes destroy almost altogether the taste of food, so that there is a very close connection between the sense of taste and the sense of smell.

The sense of taste comes to us through the tongue, which is the principal organ of taste. The remainder of our sense of taste lies in the surface of the palate and in the throat. As in the case of the other senses, the sensation of taste is given us through nerves, the ends of which are all through those parts of the tongue, the palate and the throat, which contribute to this sense. More nerves of taste are located in the back part of the tongue than on the front, and it is said that when you have to swallow a bad dose of medicine it won't taste so much if you put it on the front part of your tongue and then swallow, because there are so few tasting nerves there. The extreme tip of the tongue, however, is very thickly covered with the ends of the taste nerves. In like manner one could have the front end of the tongue cut off and still retain most of the sense of taste.

Now, in order to produce the sensation of taste, the substance to be tasted must come in contact with something which mixes with it and causes the sensation of taste. This is what happens when we taste anything. The juices or liquids which are caused to flow when anything is put into the mouth act on the substances which enter and give the taste nerves a chance to taste them. Really the nerves of taste are so placed in the mouth as to be regular guards or inspectors of what shall go into the stomach. You can see how well they are arranged. In the tip of the tongue quite a few of them; in the back part of the tongue a great many nerves, for from there the food goes into the throat, which delivers it to the stomach; then those in the palate and in the throat. They are arranged so that the taste nerves have ample opportunity to test what comes in and to give warning to the brain of what is being sent to the stomach. Sometimes the things that come into the mouth are so distasteful to the nerves of taste that they refuse to hand it over to the stomach, but instead cause the distasteful substance to be thrown out again immediately.

It is said that a good rule to follow in eating would be to swallow only such things as are pleasing to the sense of taste. On this principle many children would decide to eat nothing but candy, but do you know, if you tried that, the continuous tasting of sweets by our sense of taste nerves would cause them to repel further insertion of candy after a while. You know that too much of a good thing is bad for you, and that is what makes you feel badly when you have eaten too much of one thing.

What Happens When We See?

~HOW WE SEE THINGS~

Of course, it is the eyes with which we see things. When we think of the things with which we see, we think only of eyes, which give us our sense of vision, but there are certain forms of animal life which have no eyes but which have what are called eye spots or eye points, which are sensitive to light and which are merely spots. These eye spots may be located in any part of the body, and are often found in great numbers on the same body. These rude eyes are, however, not real eyes. They are, as has already been said, sensitive to light, but are found only in some of the very low forms of animal life which live in the water. A real eye is an organ in which the parts are so arranged that optical images may be formed.

As animal life becomes developed to a higher scale, the parts which contain the making of real eyes become more distinct although, of course, the eyes themselves are not so highly developed as in man. One of the first kinds of life which has eyes with a

definite structural character are the worms, snails, etc., though their sense of vision is more or less dim.

When we come to the family of mollusks, however, low down in the scale of life though they are, we find them to possess eyes which enable them to see almost as well as animals which have a backbone, although this kind of eyes is constructed in a very different manner than the eyes of vertebrate animals referred to. As we ascend the scale of animal life in the study of eyes, we come next to the crustaceous, which is an important division of animal life that embraces the crabs and lobsters, shrimps, crawfish, and insects such as sand-hoppers, beach-fleas, wood-lice, fish-lice, barnacles. The eyes of such animals are quite developed, but the number that each will have varies. Some have only a single eye and others two, four, six or eight, but only certain kinds of this class of life have more than two eyes. The spiders generally have the most.

In vertebrates, which is the class of animal life to which we belong, the number of eyes is almost always two and no more. The eyes are formed in special sockets in the skull, which are called eye sockets or orbits. This arrangement of placing them in a socket is of great advantage because the eye is thus protected from chance of injury except from one direction--the front. These animals have also eyelids, eyebrows and eyelashes, which serve as a further protection to the eyes.

The principal parts of the eye are arranged in a globe-like ball called the eyeball. This eyeball is movable in the socket under control of various muscles. The eyeball is almost surrounded by a membrane which is opaque in most parts, but very transparent at the front. This transparent portion of the surrounding membrane is called the cornea, and is quite hard. This is the outside coat of the eye. The second coat of membrane consists of parts of various names and contains the iris. The third coat is the retina, which is the end of the optic nerve entering the eye full from behind and expanded into a membrane which spreads out over the second coat.

The retina or optic nerve receives optical impressions focused upon it by the crystalline lens. These impressions are carried along the optic nerve to the brain, and the brain then receives the sensation of seeing the image. The eyeball is hollow, and its three surrounding coats form what is practically the same as the interior of a camera. The crystalline lens of the eye acts the same as the lens in the camera. This crystalline lens is suspended within the eyeball right in front of the transparent opening in the front of the eyeball, and when the rays of light strike this lens it focuses them on the retina, which is the same as the film in your camera.

Why Can We Hear?

We can hear because nature has provided us with a very wonderful organ called the ear and which catches the sound waves that come through the air into the ear and make a part of the ear vibrate.

In man and mammals the ear is generally found on the outside of the body, but the principal part of the ear is located within the skull. What we call ears are only the funnel-shaped extensions on the outside of the head which are not so very important so far as hearing is concerned, because they only help the real ear to hear more easily. The outside of the ear gathers in the sound waves and, because it is much larger than the little hole which takes the sounds in to the real ear, we can detect more sounds by having this funnel-shaped arrangement on the outside.

The inside of the ear contains an eardrum or tympanum which is separated from the outside part of the ear by a membrane. Behind this eardrum is the real hearing part of the ear in a labyrinth containing the nerves of hearing.

Now, when a sound wave strikes the membrane which hangs over the opening before the eardrum, the membrane vibrates and transmits the sound wave through the eardrum into the inner ear which contains the ends of the nerves by which we hear. These nerves, on receiving the sensation, transmit it to the brain which thus records the impression of sounds.

As we descend the scale of animal life from the mammals downward, the ear becomes a more and more simple organ. In the vertebrates which are not mammals, there is no external ear at all, and we find great simplifications of the ear the lower down in the scale we go.

What Is a Totem Pole For?

Before people had individual names, the savage people who lived in clans or tribes referred to themselves in the name of some natural object, usually an animal which they assumed as the name or emblem of the clan or tribe. These names never applied to one individual more than another, but only to the clan or tribe, so that everyone in a tribe which had taken the “wolf” for its emblem was known as “Wolf.” Later on they began to distinguish individuals by giving them additional names characteristic of the individual,

such as “Lonely Wolf,” “Growling Wolf,” or other names. The name of this animal was then the emblem of one tribe. They, therefore, placed this emblem upon their bodies, their clothes, utensils, etc. Through this, these emblems also became at times idols of worship and so they erected poles upon which their emblems were engraved. The word totem is a North American Indian word meaning “family token.” The tribes called themselves after animals from which they believed themselves descended.

Where Does a Flower Get Its Perfume?

The perfume or smell of the flower comes from within the plant itself. The perfume arises from an oil which the plant makes, and just as there are many kinds of flowers, so almost every flower has a different smell. Of course, flowers belonging to the same family or species are likely to develop different smells. The oils produced are what are known as the volatile oils, which means “flying oils,” because, if extracted from the flower and placed in a bottle and the cork left out, they will vanish into the air. Without this quality we could not, of course, smell them at all.

Why Do Flowers Have Perfumes?

Man uses these oils to provide himself with perfumes, but the plant or flower has another purpose than this. The perfume is not made for man’s use, but for the use of the plant itself. In the plant and flower world the smell of the plant which is in the flower is a part of the scheme whereby plants reproduce themselves.

Every plant in order to reproduce itself must produce a seed. The flowers are in most cases the advance agent of the coming seed. Each flower produces within itself a little powder called the pollen, but as plants are like people--also male and female--they are dependent upon each other for the production of a perfect seed. Some of the pollen from the male plant must be mixed with the pollen of the female plant before a perfect seed results.

How Do Flowers Produce Seeds?

Naturally, the nearest male plant to a female plant may be quite some distance off. How, then, is the pollen from the male plant to mix with the pollen of the female plant? In some cases it is the wind which blows the pollen powder from one to the other, and this thus leaves the development of a perfect seed from a perfect flower open to chance. In the case of perfumed flowers, however, which are mostly low-growing plants, the wind cannot be depended upon. So nature gives to such plants the power to make the perfumed oil and the busy bee does the rest. The perfume being a flying oil rises up into the air and attracts the bee. He is gathering honey and visits in turn all the flowers to which he is attracted. He lights on a male flower and gathers in his honey, and incidentally acquires on his legs, without intending to do so, some of the pollen of the male flower. Then he flies about to the next flower, and to others, and sooner or later he will come across a female flower of the same kind as that from which he secured the pollen on his legs. When he thus enters the female flower, the pollen on his legs mixes with the pollen of the same kind of the female flower, and quite unintentionally the bee helps thus to make the perfect seed. It is not a part of a bee’s business to do this carrying. It only happens that he does this in connection with his regular business of gathering honey. It is a wonderful thing which may be noted here that the pollen from a male of any flower will not mix with the pollen of the female of any other kind of flower, but that the same kinds only have attractions for each other. Flowers are given these attractive perfumes in order that they may attract the bees and other insects in this way. The plants or flowers which grow closest to the ground have generally the strongest and most far-reaching smells. This is so that they will not be overlooked.

Why Are Leaves Not All the Same Shape?

Leaves are of different shapes because they belong to different families of plants or trees. They are a good deal like people in this respect. Hardly two people in the world look exactly alike, but there is a distinct family resemblance in members of the same family. It is difficult to say just what happens inside the tree to determine the shape of the leaf and that causes them to possess different shapes from others. The shape of the leaf is a mark of identification of the family to which the tree or plant belongs, just as you can tell from a dog’s ears and from other characteristics what his breeding has been. In the case of plants and trees however it is quite probable that the shape and texture of the leaves has been developed as the result of the conditions under which the plant grows. A plant or tree throws off oxygen and takes in carbonic acid gas through the surface of the leaves. To thrive and be healthy it must secure just the proper amount of this food and as the quantity of food taken in depends upon the amount of surface exposed through the leaves, each particular tree or plant has developed in its own direction in this respect until this feature of their structures

has been adjusted properly to their needs. It is a good deal like the radiation of heat in your home.

Why Are Some Radiators Longer Than Others?

When the plumber gets ready to put in the radiators in the home he figures the cubic measurements of the room and then puts in a radiator, the outside surface of whose pipes, is in the right proportion to throw off sufficient heat to fill the room or heat all the air in the room. It requires a certain number of square inches of radiator surface to heat each cubic foot of air space and a good plumber can figure this to a nicety. If he puts in a radiator however that has not sufficient number of square inches on the outside of the pipes, the room will not be heated properly. In the same way, the trees, require that their leaves have a certain amount of square inches of surface space in proportion to the size of the tree, to enable them to do what is required of them and this is arranged by nature so that the trees grow naturally, and no doubt the shape of the leaves has something to do with this.

What Makes Roses Red?

All roses are not red. Some are white and others pink or of still another color. The color of the rose, and in fact the color of all flowers is due to the way they absorb and reflect the sunlight. In the case of the red rose, the something in the plant that determines the color, absorbs all the other colors in the sunlight and reflects the pure red rays and that makes the color of the red rose. You cannot see the color of any flower when it is perfectly dark. That is because they have no color of their own, but only the colors which they reflect when in the sunlight or some other light. The question of colors is more fully explained in another part of the book.

Why Do Plants and Trees Grow Up Instead of Down?

As a matter of fact plants and trees do grow downward as well as up. There is a part of each called the root whose business it is to grow down and take certain things necessary to the life of the tree out of the ground. But the part we see above the ground and which is the part we generally think of only when we think of plants or trees.

The tree or plant, in order to grow properly, and eventually produce flowers and perfect seeds, must have sunshine and carbonic acid gas, and it is the business of the leaves and other parts above the ground to get these out of the air for the good of the plant or tree. So they start to grow toward the sun. It is easy to prove how a plant will turn toward the light. Take notice of the plants in the flower pots at home. Set one of them on the window sill inside the window where the sun can shine on it and notice how quickly the leaves and branches will be bent over against the window pane. Turn it completely around then so that the plant leans away from the sunlight and watch it for a day or two. Before long you will find that it has not only straightened itself completely out but started to lean toward the window glass again so as to get as near the sun as possible. Most plants, if kept where the sunlight cannot touch them, will die. The sunlight is a necessary part of their lives.

What Becomes of the Plants and Flowers in Winter?

A great many, in fact the large percentage of plants, live only during one season. This kind of plant actually dies completely after, in the natural course of growth and flowering, it has produced its seed which is the method by which such plants are reproduced. Other plants only appear to die in the winter. Parts of them, such as the leaves and flowers actually die, but the roots and stalks of such plants do not die in winter. The part that represents the life in them goes to sleep and lies dormant until the light and warmth of summer bring forth the leaves and flowers again.

The flowers, however, always die and the same flowers never appear again but others just like them appear in their places.

Even in hot countries where there is no winter, the plants must go through a period of rest or sleep, although this change is not so marked in plants which grow in these hot countries.

How Can Some Plants Climb a Smooth Wall?

To get at the answer to this question, we should pick out one kind of plant like the creeping ivy vine. If we examine same as it climbs a brick wall, we find that it sends out little shoots which attach themselves around the little rough places in the bricks of the wall which, if examined under a microscope are quite large apparently--at least they are large enough for the tiny creepers of the ivy to hold on to. Of course, if there were only one little “shoot” to reach out and take hold of the rough spots in the wall, the vine

could not cling to the wall, but the vine puts out a great many of these shoots--which it would perhaps be best to call “clingers” and as each helps a little to hold on, the great number all holding on together enable a quite heavy vine to hang on to an apparently smooth wall.

Some vines have actually the ability to send out little suckers which are made on the same principle as the boys’ sucker (a circular piece of leather with string attached to the middle with which a boy can pick up stones) and such plants can cling to and climb up an almost perfectly smooth wall.

What Are the Thorns on Roses and Other Plants Good For?

The thorns of roses and other plants which have thorns originally grew for the purpose of enabling the plants to fasten themselves on to other things thus helping them to climb. Many plants with thorns are permitted to grow now in places where they can use their thorns for climbing but many others with thorns are cut down by the gardener to make the plants shapely and to make them produce more flowers and less branches, but they keep on growing their thorns just the same.

Do Plants Breathe?

Yes, indeed, plants do breathe. To breathe is just as important to the life of a plant as it is to a boy or girl. Plants do not have lungs like boys and girls and grown up people, but they find it necessary to breathe. You know, of course, that fishes breathe, but they haven’t any lungs either, even though they belong to the animal kingdom. Fishes do not, however, breathe the air in the same form as we do because they must use the air which they find in the water. That is why we say fishes drown when on the land. They cannot breathe air in the form in which we are able to use it any more than people can breathe the air in the water.

Breathing, however, is necessary to all living things and the gas which we take in when breathing is oxygen. There is oxygen in the water as well as in the air. Things which live in the air take their oxygen out of the air and things which live in the water get their oxygen out of the water. For this purpose it is necessary for plants and animals that live under the water to have a breathing apparatus especially adapted for getting oxygen out of the water.

What Happens When Breathing Occurs?

The act of breathing consists really of two actions. Taking something into the body and expelling something. Every living thing inhales and expels in breathing. We take in oxygen and expel it again but when it comes out it has added something to it and the combination or result is carbonic acid gas--so we take in oxygen and expel carbonic acid gas.

How Do Plants Breathe?

The lungs of a plant, or what the plant breathes with corresponding to our lungs, are located in the leaves of the plant. Under a magnifying glass we can see the lungs of the leaf quite clearly. In addition to this we know that plants breathe, because if we put them in a vacuum where there is no air they die very quickly. The plant needs air or it will suffocate just as any animal will suffocate under similar conditions. Plants, however, do not make use of the oxygen as they find it in the air. They live on the carbon which they find in the air mixed with oxygen. What happens then is this. The plants take in through their lungs in the leaves carbonic acid gas from which they take the carbon and use it as food, and throw off the oxygen which they cannot use. Human beings and other animals take the oxygen into their lungs and use it and expel carbonic acid gas. The result is that each kind of life is dependent upon the other. If it were not for the plant life, men and other animals would find it difficult perhaps to find sufficient oxygen in the air to keep them alive, and if it were not for the carbonic acid gas which the animals throw off, plants and other vegetable life would have great difficulty in finding sufficient carbonic acid gas to go around.

Why Do Plants Need Sunlight?

Most plants, if placed where no light from the sun can reach them, will die very quickly. To prove that a plant needs the sunlight we have only to place it in a dark corner of the cellar and notice how soon it dies. In fact if it were not for sunlight there would be no life on earth at all. The plant or tree drinks in sunlight through the surface of the leaves. In fact the ability to take in sunlight constitutes the real life of the tree or plant. Leaves grow thin and flat in order that as much surface as possible may be exposed to the sunlight.

If a leaf were curled up like a hoop only a part of the outside surface would be exposed to the sunlight and the amount of life that a leaf could supply to the rest of the tree would be much less. The leaf is so constructed that when the sunlight strikes down upon its green surface, it changes the carbonic acid gas which it drinks in, into its elements, i.e., it takes out the carbon which goes into the body of the plant and combining with other food and water supplied by the roots causes the plant or tree to grow and then returns the oxygen part of the carbonic acid gas to the air.

Why Does Milk Turn Sour?

The milk turns sour because a little microbe, known as the milk microbe gets into it, and being very fond of the sugar which is in the milk, turns this sugar into an acid.

If we could keep milk entirely away from the air after the cow is milked, it would not turn sour, but as soon as it is exposed to the air these microbes which are constantly in the air, drop into the milk. They are alive, although invisible to the naked eye. If when they drop into the milk it is warm enough for them to get in their work so to speak, they fall upon the sugar in the milk and turn it into the acid. Their attempt to sour the milk can be overcome by keeping the milk at a low temperature in the refrigerator, but as soon as the milk is taken out of the refrigerator and left out long enough to become warm, the microbe begins to work and the milk cannot be made sweet again. If the milk is boiled as soon or shortly after the cow is milked, the sugar in the milk is changed in such a way that the microbe cannot feed upon it.

The Story in a Rug

What Are Carpets and Rugs Made Of?

The choicest wool of the world is used in the manufacture of carpet. In order to give satisfactory service carpet must be made of wool that is of a tough quality and has a long fiber. Such wool is not produced in America, and the markets of the distant lands that supply it are practically exhausted to supply the American manufacturers. Most of the wool used comes from Northern Russia, Siberia and China. It is shipped in bales. When it arrives at the mill there is much to be done before the wool is ready for any process of manufacturing.

How Long Have People Used Carpets?

The art of weaving stands foremost among the ancient industries. It came into being in the sunrise lands of the East where color has endless charm and variety and where figure is made to serve the purpose of fact and fancy. The art of weaving rugs is older than Egyptian civilization. Stone carvings made when Egypt was yet unborn were reproduced in rugs.

At what period the loom was first used is impossible to tell. An ancient Jewish legend claims that Naamah, daughter of Tubal-Cain, was the inventor of the process of weaving threads into cloth. There are other indications that the ancient Hebrews were the first weavers. Mythology also tells of beautiful maidens weaving exquisite patterns for the gods. Most of us are familiar with the story of Jason who set sail on the Argo in search of the Golden Fleece, arrived at the kingdom of Aeetes, won the hand of Medea, the daughter of Aeetes, who eloped with him after he had secured the coveted fleece.

The first hands busy at the weaving craft undoubtedly were those of women. Chaldean gossip, repeated in history relates that Sardanphulees, an ancient Greek king, was often seen in woman’s garb carding purple wool from which his wives wrought rugs for floor coverings for the palace. Homer shows Helen of Troy setting the tale of her people’s war in the woof of her web, and also tells with Virgil of rugs that were laid under the thrones of kings or upon chariot horses. Ancient Hindu hymns show that these people made their textile fabrics studies of great beauty. The woman in the Proverbs of Solomon says: “I have woven my bed with cords; I have covered it with painted tapestry from Egypt.” One learns from the writings of Pliny of the large money value of rugs in ancient times. He wrote at length of a vast rug displayed at a banquet of Ptolemy Philadelphius, the value of which was placed at a fabulous sum.

A later writer tells of the love of Cleopatra for rich rugs and tapestries that were woven in her palace or in the countries to the East. On the occasions of her meeting with Cæsar and Antony, the Egyptian queen enveloped herself in a superb rug which she had

woven especially for the purpose of showing her renowned beauty to the best advantage. Akhar, emperor of Hindostan, spread a knowledge of the art of weaving throughout India.

The earlier phases of the art of weaving may be traced through the land of the Pharaohs to Northern Africa, Southwestern Asia, and finally into the dawn of the Aryan civilization. The loom has not been materially changed, and it may be seen to-day as it was in the time when the priests of Heliopolis decorated the shrines of their gods with magnificent carpets and when Delilah wove the hair of Samson with her web and fastened it with a wooden pin. The ancient weavers attained high artistic standards in their fabrics. Pliny tells of Babylonian couch covers that had all the beauty of paintings and sold for great fortunes to the ancient Asiatic kings.

In all ages fine rugs have been used for religious purposes. Early writings describe the use of rugs on the holy cars of pilgrimage to Mecca, at the tomb of the prophet at Medinah and throughout the mosques of the Orient. The abbot Egelric gave to the church at Croyland, before the year 892, two large rugs to be laid before the high altar on great festivals. At later periods rugs were used for similar purposes in the cathedrals of Southern Europe.

The Oriental people ever have been devoted to symbols and naturally wove them into their fabrics. Their textiles were made to reproduce mythological stories in which the fauna and flora of a country figured prominently. There was the symbolism of form, color and animal life, of trees and flowers, of faith, and earthly and heavenly existence. The symbols were made to illustrate the conflict between light and darkness, the evolution of life, the decay of death and the immortality that awaits the blessed in paradise.

What Do the Designs in Rugs Mean?

Since many of the figures of ancient rug-weaving are retained in modern rug designs, the following list of meanings of ancient Oriental symbols used in rug-weaving may be interesting as a key to the stories that are said to appear in many rugs of Oriental design:

Asp--intelligence Bat--duration Bee--immortality Beetle--earthly life Blossom--life Boat--serene spirit Butterfly--soil Crescent--celestial virgin Crocodile--deity Dove--love Eagle--creation Egg--life Feather--truth Goose--child Lizard--wisdom Palm tree--immortality Sail of vessel--breath Wheel--deity Lion--power Ass--humility Butterfly--beneficence of summer Jug--knowledge Ox--patience Hawk--power Lotus--the sun Pine-cone--fire Zigzag--water Leopard--fame Sword--force Serpent--desire Bird--spirit Owl--wisdom Pig--kindness

Such are the traditions that the makers of modern rugs must live up to. The art of the centuries has been revealed in the rugs of many nations, and the rug-maker of to-day must uphold the standards of an art that undoubtedly takes rank with the great arts. Where a valuable painting goes into the home of one millionaire, thousands of rugs made from an original design of unquestioned art and beauty go into homes the country over to give warmth, comfort and beauty, delighting housewives and imparting a sense of coziness and elegance.

According to students of the art of weaving, the perfection of this art was attained about the sixteenth century, after many centuries of slow growth. Since then weaving as an art has been broadened and given a wider scope by means of processes invented for a cheaper production of rugs in all the beauty of their original designs. But there also has developed a modern school of rug and carpet designing that in itself represents no mean standard of art. Many of the less expensive grades of American rugs and carpets, for example, are of designs created by artists of this modern school of weaving designs whose work is of a high degree of artistic excellence.

[Illustration: HOW OUR GRANDMOTHERS MADE RAG CARPETS

MAKING THE OLD RAG CARPET.]

A quarter of a century ago many homes had rugs woven by the housewives with their spinning-wheels, or no floor coverings, except crude cloths made of rags. These homes, of course, were those of families in moderate circumstances, which to-day can have their attractive and comfort-giving rugs of the less expensive grades of tapestry carpet, Axminster or of the various other grades of carpet manufactured at a range of prices within the financial reach of people of modest means.

It is only a step from the ancient weaving of rugs, with all the color, glamor and romance that attached to rug-weaving in the ancient days, to the manufacture of rugs in America to-day. There is no romance attached to the making of rugs and carpets in America, except the romance of industrial achievement; but the American rug-maker is as careful of the quality and beauty of his product as was the ancient weaver, and the best standards of ancient weaving have been realized in the manufacture of rugs and carpets in

America to-day.

Why Did the Ancients Make Rugs?

It is only a rug, several yards of woven threads, a design that few can understand--a simple thing, to be sure; yet what a lot of history and memories and traditions it carries! Merely a strip of carpet, with strange figures, beautiful though meaningless, a product of modern invention like many another, some may think. But the story of a rug may go back through many centuries to ancient times of opulent splendor, when wars were waged and kingdoms created and shattered for the beauty of a woman; when gorgeous palaces were raised and great spectacles of art were shown to inspire the world for thousands of years.

Only a rug, but a relic of a rich and glowing past! For in those distant days of war and pageantry, an era more classic than our own, history and romance were woven into the rug. The patterns and designs told great stories of wars and loves that swept nations away and created great new empires and related vivid accounts of intrigue and tragedy that determined history and inspired the immortal works of poets and dramatists. The rug in the ancient times was also used for religious symbolism, and sacred doctrines were inscribed in the woven figures.

Of all the arts none has been as close to the lives and history of the peoples of the earth as the art of weaving. Songs and stories of these peoples and their national achievements have been immortalized through their woven fabrics. Generations have learned of the great deeds of their forefathers through the historical accounts woven into rugs. And in the days of the early Greeks, Hebrews and Egyptians and on through the succeeding centuries until the middle ages the rug was used as a symbolical part of state, religious and romantic ceremonies.

What Makes Some Rugs so Valuable?

The reason many rugs are valued at so high a price in money is largely due to the skill of the artist or designer, just as a painting becomes valuable because the artist who painted it has succeeded in producing a remarkable result. The question of rarity also enters largely into the value of rugs. The great artist weavers of the past who worked for love of their art rather than for the money they might secure by disposing of their masterpieces, are dead, and they have had no successors. Then, also, the rug becomes valuable by reason of the amount of time and labor put into it. Many valuable rugs take years to produce, because the artist must do all his work by hand practically and tie his different colored yarns together just so, or the pattern will not come right. These knots may occur every inch or sometimes even less than an inch, and there will be thousands of hand knots in one rug.

[Illustration: MAKING TURKISH RUGS.]

[Illustration: THE OLDER THEY ARE THE MORE HIGHLY PRIZED

The above is a typical Chinese rug, containing symbolical emblems.

This is an antique and is of a class that sells sometimes as high as $5,000, its rarity of design, beauty in colors, and scarcity enhances its value.]

[Illustration: This is an American machine-made interpretation of a Chinese rug. The ground is a rich gold coloring, the figures being in ecru, dark blue, terra cotta and light blue. It is a beautiful rug, and one of the finest examples of loom-tufted goods ever produced.]

[Illustration: WHERE THE BEST PERSIAN RUGS ARE MADE

This antique Persian was made in the district of Kurdistan, in Western Persia. The general effect is handsome, although the design is crude. The ground is of a deep rich red, and top colors of dark blue and ecru.

The most valuable Persian rugs come from Kurdistan, Khurasan, Peraghan and Karman. The most highly prized come from Kurdistan. The pattern does not show a uniform ground of flowers or other objects, but looks more like a field of wild flowers in the spring, which is very appropriate as a design for anything that is to be walked upon. It is astonishing what wonderful artistic ability is displayed by some of the members of these wild nomadic Persian people. The carpets and rugs are woven on a simple frame on which the warp is stretched. The woof, or cross threads, consist of short threads woven into the warp with the fingers and without the use of a shuttle. Then a sort of comb is pressed against the loose row of cross threads to tighten it. The weaver sits with the back of the rug towards him, so that he depends entirely on his memory to produce a perfect pattern.]

[Illustration: This rug is an American copy of a typical Kurdistan. It is marvellous how well the effect in colors and design are reproduced in this domestic rug.]

[Illustration: HOW WE IMITATE POPULAR DESIGNS BY MACHINERY

This Tabriz reproduction has all the characteristics of the genuine rug in both design and color. The ground is of a soft rose with figures olives, ivory and deep blue.]

[Illustration: This is a copy of an old piece of a rug in the Kensington Museum, London, which is 500 to 600 years old. The design is very interesting on account of the symbolical figures which cover the ground.]

[Illustration: WOOL-PICKING MACHINE.]

The Making of Carpets

How Are Modern Rugs and Carpets Made?

The best way to learn of this is for us to take a brief visit to one of the largest carpet factories, where we will assume we have already arrived.

There is a sharp whistle, then an outlet of steam, the clang of a bell and a locomotive rolls around the curve of the spur-track into the factory yard. Attached to it are several freight cars that only the day before received their cargoes at the New York docks fresh from steamships coming from foreign lands. Inside the yard, the engine comes to a stop alongside a warehouse. Sturdy men unlock the doors of the cars and begin pulling out bales of the imported wool.

This is the first step in the evolution of a rug. Between the arrival of the rough wool at the warehouse and the placing in the stock room of the finished rug, splendidly woven after an artistic design shown in attractive colors, many interesting processes are followed. It is sufficient to state that few people looking at rugs of the Saxony, or Axminster or Tapestry type realize the high degree of mechanical science and artistic perception that have been brought to bear in the manufacture of these rugs.

After the arrival of the wool there are many steps to be taken until the skeins of yarn receive their coloring treatment in the dye-house and, at the bidding of the great machine, assemble themselves in the beautiful designs that the artists have created. Though there are many details of work in the development of a rug, they have been so well mastered that the employes in charge of every stage of the rug’s evolution give to their work a nicety of attention in little time that careful training and scientific understanding alone can supply.

The travel-stained covers of the bales are removed. The heavy bulk is broken and the tightly-compressed bales loosened. Then the wool is fed into the washing-machine, and after that goes into the picking-machine. The process of cleansing the wool is an elaborate one, for it is so full of dirt and grease that several waters and several operations are necessary to its final appearance in a white and fleecy condition. After the last washing the wool is lifted to a drying-room, where the heat from steam-coils is forced through it by means of blowers.

The wool now passes to the sorting-room, where the blends are carefully made before it goes to the machine which tears the wool fibers apart, and gets them in shape for the carding and combing processes. Next the wool is blown into a spinning mill. The wool is now ready to be converted into yarn. It passes through a picking-machine, which blends the different grades of the raw material, selecting the strands as to fiber and color. Then it is refined and purified.

[Illustration: CARDING MACHINE]

Through tubes the wool is forced to the carding-room by means of air pressure. In passing through the cards it is carefully weighed to secure evenness in the yarn. Leaving the carding machine, the wool is taken to the floor above, where the big spools of yarn reach the combing machine for the next process. This machine separates the long from the short fibers. The strands of wool are still thick and must go through another process before they are ready to be made into yarn. They are finally united and given sufficient strength to stand the weaving process. As the visitor sees the strands of yarn first appear on the machine they resemble rolls of smoke.

[Illustration: DYEING THE YARN]

~HOW THE YARN FOR CARPETS IS DYED~

The yarn next appears on rows of spindles in the mule-room, six hundred feet long, where the yarn is twisted and brought to its final stage. The yarn now is ready for the dye-house. Here the atmosphere is very dense. Clouds of steam rise from the many vats of boiling dyes. The yarn receives the coloring for which it is intended, or is bleached in an adjoining department, and then is transferred on poles to the drying-room, after passing through a steaming process which sets the color. Next it passes on an electric conveyor to the weave-shop.

Considerable skill is required in the weaving process. The assembling of the yarns and matching of colors require expert attention. The skeins of yarn are wound on spools, which are put in sets back of the looms, each color or set representing one “frame” of color in the rug. By the famous Jacquard motion of cards each color wanted in the surface of the rug is pulled up in its proper place, the other frame color laying in the back of the rug. The mechanical process is a remarkable sight. As the pattern forms itself from the mechanical devices, the onlooker is struck with the wonder of it.

[Illustration: HOW A CARPET IS WOVEN BY MACHINERY

WEAVING A RUG BY MACHINERY]

[Illustration: 10,000,000 YARDS OF CARPET PER YEAR FROM ONE FACTORY

This picture shows the plant of one of the largest carpet factories in the United States at Thompsonville, Conn. From the looms of these mills are annually produced ten-million yards of the twenty-five different grades of carpet manufactured by this concern.

Imagine a strip of carpet across the United States at its widest part, the Forty-second latitude--a strip of “Hartford Saxony”, say, stretching from the Atlantic seaboard to the Pacific coast; and then another carpet strip the length of the United States, where this country is the longest--i. e., from the Northern boundary of the state of Minnesota to the Southern boundary of the state of Texas; then imagine one more strip stretching from Chicago to New Orleans, and finally a connection between the two latter strips at about the vicinity of St. Louis.

With a mental picture of this vast country thus stripped with carpet, you wonder if there is that much carpet in the world. It seems incredible that this great sweep of land could be measured with carpet--and yet enough material comes every year from the looms of one carpet factory alone in this country to strip the United States East and West, and North and South as indicated above.]

The weave is now completed; the rug comes out. But it is rough and has to be finished. It is passed through a machine that removes the roughness of the face as a lawn-mower cuts away the top-grass. The ends are finished, and the carpet is complete.

~SOME DESIGNS STAMPED ON YARN BEFORE WEAVING~

The pattern of tapestry carpet is obtained by printing the colors to appear in the design on the yarn which forms the face before the weaving is started, by means of large drums. After all rugs leave the weave-shop a force of skilled women examine them carefully to make sure that there are no defects. Every yard of the annual output of carpet and rugs is inspected five times before it leaves the factory.

[Illustration: EXAMINING AND REPAIRING]

[Illustration: PACKING FOR SHIPMENT]

Why Do I Yawn?

When you yawn, you do so because you have not been breathing quite properly and for some reason or other your blood supply has not been getting sufficient oxygen through the air which has been taken into your lungs. Nature’s way, in this instance, is to call for a big intake of air all at one time, and since it is important at such times that a large quantity of air should be supplied to the lungs at once, nature has so arranged matters that certain muscles shall cause you to open your mouth wide and take in as much air as you can at one time, and also has arranged so that it is almost impossible to keep from yawning when the demand for it is once made. The yawn is controlled by a part of our nerve structure which looks after the breathing apparatus.

The satisfaction we feel after a wholesome yawn is due to the fact that having replied to nature’s demand that we bring in more air, our blood secures the oxygen which it needs and we feel the effect of better blood in our arteries at once.

A peculiar thing about the process of yawning is that one person in a room yawning will quite likely set all or nearly all the others to yawning also. There seems to be no explanation of this excepting that when a number of people are in one room and one of them begins to yawn, the others do so, not because they perceive the first yawn so much as the probable fact that the air in the room has become so poor that there is not enough good air for all the people in it, breathing normally, and many of them are forced to yawn at about the same time.

Where Do Living Things Come From?

This is a big subject, but a very interesting one. To understand it fully we must begin at the very beginning of the world.

God made first of all the rocks, the mountains, the sun, the moon, the stars, the soil, and put the water in the lakes, rivers and oceans. This took a long time, but they had to be there before the living things could begin to be.

What is Inorganic Matter?

This thing we have spoken of is called inorganic matter, which means “without life,” and everything in the world which has no life is called inorganic matter. These things do not die, and for that reason do not have to be replaced. The form and appearance of inorganic matter and its location is often changed by man or other causes, but even when man burns the coal which he has dug up out of the ground in the furnace, no part of it is destroyed. Some of it is turned into smoke and gas and some of it is turned into ashes, while every other particle which went to make up the coal originally is still in existence. It remains as inorganic matter in some form or other.

Where Did Life Begin on Earth?

After the inorganic things had been made and the earth was ready for life, the different kinds of living things which we find on the earth began to exist. These are called organic objects, which means objects “with life.” The first living things to appear were the bushes, the grass, the garden vegetables, the flowers, trees, and all the kinds of life which we ordinarily think of as growing things.

This division of living things makes up what we call the vegetable kingdom, and in a general way of classing it is the kind of life which cannot move about from place to place and which has not a sense of feeling, or any of the other senses, seeing, hearing, tasting or smelling.

After this division of life had been established the world was ready for the other and more important form of life--the fishes, the birds, cats, dogs, horses, cows, with others that we call domestic animals, and also the lions, tigers, elephants and others which constitute the division of wild animals.

This kind of life was given some or all of the five senses, but not all classes of animal life possess all these senses. Some of the lower forms of animal life, like the oysters, clams, in the fish family, cannot see, hear, smell or taste. They can only feel; others are able to do more of these things, and many have all of the five senses.

When Did Man Begin to Live?

Man was not created until all the other living things on earth had been started, and he was given additional powers so that he might become the ruler of all the other living things, principally because he was given a brain with power to think, reason and originate.

Why Must Life Be Reproduced?

Life must be reproduced because living things die. They have power to live only for a certain length of time. The other life in the world is used to provide food for man, and if there were no way of reproducing life it would not be long before man had eaten all the vegetables and the animals too, and would himself then starve to death.

To avoid such a calamity God put into each living thing, both vegetables and animals, a power to cause other things of the same kind as itself to grow. This is called the power of reproduction. With this power each kind of living thing can bring other specimens of the same kind into the world and each kind of living thing can do this without aid from any other kind of life.

The trees, the flowers, and other kinds of vegetable life would reproduce themselves without the aid of man, as would also the fishes and other kinds of animal life. Man, however, just to have things conveniently at hand, uses his power over other life to cause his vegetables to grow near where he lives, and keep the animals which he wishes to use as food in some place where he doesn't have to hunt for them every time he wishes meat for his table. This, however, he does only with the animals which he has domesticated or tamed. When he wants meat from the animals which are still wild he must hunt for them as he used to do.

Each kind of life has the power, however, to reproduce only its own kind. If you plant a peach stone you will sooner or later have a peach tree which will bear peaches, and these peaches from the young tree will look and taste just like the peach whose pit or stone you planted. There may be other kinds of fruit trees all about, and also trees which do not bear fruit. All of the trees secure the food upon which they live and grow from the same soil. Even the grass under your peach tree eats the same things as your peach tree, but it remains always true that things in the vegetable kingdom will grow only to be like the thing from which it came.

Have Plants Fathers and Mothers?

The little trees grow up to be exactly like their fathers and mothers (for they have fathers and mothers), which is something all living things must have. These are not the same kind of fathers, or mothers either, that a boy or girl has, exactly, but they are parents just the same. So far as the trees, flowers and plants are concerned we call the parents father and mother natures, which is a term used merely to keep you from confusing vegetable life fathers and mothers with the regular kind.

In the vegetable kingdom you cannot always see these father and mother natures, which enable them to reproduce their kind of life, but everything in the vegetable and also in the animal kingdom has them.

How Do Plants Reproduce Life?

In the spring we put seeds into the ground and later on plants grow up where the seeds were planted, and later the flowers come. The seeds contain the baby plants, which come to life, and after bursting the covering of the seed, unfold and grow up into plants if placed in the ground, where they can obtain the proper amount of warmth and moisture to give them a start.

Why Do Plants Have Seeds?

To get at this subject in the best manner we must study first how plants produce seeds and what happens. The power in a plant to make another plant like it grow comes from the flower. Ordinarily we think of the flowers as beautiful to look at and delightful to smell, but the flowers do not grow for the mere purpose of being beautiful, but are for a more useful purpose--to develop a seed which, when planted, will produce another plant. The machinery for producing a perfect seed is in the flower or blossom. Every flower has a definite plan of construction. The leaves and colors vary, but the plan for a perfect flower is always there. The petals which are generally colored are called the _crown_. When you pluck off the petals you see a number of green leaves at the bottom where the petals were attached. These form what is called the _calyx_, and help to hold the petals in place. Inside the flower are little stems which grow to the petals. These are called _stamens_. Every one of these little stems is hollow, and if you split one open you will discover a _fine powder_. This powder is called _pollen_, and is the "father" nature of the plant. In the calyx, the part we had left after we plucked off the petals, is the "mother" nature of the plant. The main part of the mother nature is the stem of the flower called the _ovary_, and this is where the seeds grow. These seeds in the ovary, however, will not become perfect seeds unless some of the pollen from the "father" nature of the plant touches them and fertilizes them.

At the proper age of the flower some of this pollen powder passes into the ovary and fertilizes the seeds and makes them good seeds. This is only one kind of flower, however. In this kind the father and mother natures are in the same flower. In other kinds of plants the father and mother natures are found on different parts of the same plant.

Why Does an Ear of Corn Have Silk?

The corn plant is one of this kind. You know what it looks like--a tall plant, generally six or seven feet high. The ears of corn grow out of the side of the corn stalk. The ear is covered with husks and out of the end of the ear hangs a bunch of brown silk threads which we term corn silk. Up at the top of the plant you will see the tassel, but you may not have known that this is the flower of the corn plant. The tassel or flower in this case contains the "father nature" of the corn plant, and the ear of corn contains the "mother nature." The husks on the outside of the ear of corn protect the grains of corn on the ear inside and keep them tender. The ear of

corn is really the ovary of the corn plant, because that is where the seeds grow. You will guess, of course, that the grains of corn on the ear are but seeds of the plant. Were you to examine one of these ears of corn on the plant when it had just started to form you would find no kernels on the cob, but only little marks which indicated where the grains of corn are expected to grow, but if you want to know, then, how many grains of corn were expected to grow on the ear, you could easily tell by counting the little silk threads which you see on the cob and which stick out over the end. There will be a thread of silk for each grain of corn that is expected to grow.

Every grain of corn must receive some of the pollen powder from the tassel or father nature at the top of the corn plant or it will not develop into a nice large, juicy kernel.

How Does the Pollen Touch the Grain of Corn?

Before the kernels of corn grow the tassel is in bloom. The wind blows and shakes the pollen powder off of the tassel and the powder falls on the ends of the silk which stick out of the little ear of corn to be. Each thread of silk then carries a little of the powder down to the spot on the ear where it is attached and thus the grain of corn receives the fertilizing necessary to develop it into a ripe seed. If you leave the ear of corn alone the kernel will eventually become yellow and hard and can then be planted and will produce other corn plants. Man, however, finds the ear of corn a delightful food, if taken at a time when the seeds are fully grown but not yet ripened into perfect seeds. At this stage the grains of corn would not grow up again if planted, because they have not yet become perfect seeds.

Do Father and Mother Plants Always Live Together?

We come now to the kinds of plants on which the “father” and “mother” natures are on different plants of the same kind. At times they will grow side by side, at other times they will be in the same field, but very often they grow at quite a distance from each other. In some instances the nearest father tree will be even miles away from the mother tree of the same kind. But in any event the pollen from the father nature must reach the mother nature of the plant or tree before a perfect seed can be produced. In cases of this kind the father nature will be on one tree or plant and the ovary or mother nature on another. The wind helps out nature in some of these cases by blowing the pollen of the father plant to the ovary of the mother plant. In many other instances the bees and insects help.

Why Do Flowers Have Smells?

Where the bees do this it is because the bee has been visiting the flowers in his search for honey. They do not fly from flower to flower for the purpose of uniting the mother and father natures of plants, but they help the flowers incidentally while getting the honey for which they are searching. In gathering his honey the busy bee will go all over the father flower and get his legs all covered with pollen powder. Sooner or later he comes to a mother flower of the same kind of plant or tree from which he has father pollen on his legs, and, still bent on gathering honey, he incidentally rubs the pollen powder on to the ovary of the mother flower and the fertilization takes place. The wonderful thing about this is that the father pollen of one kind of a plant will not fertilize the mother nature of another kind of plant. To illustrate this, if a bee carrying pollen on his legs from a walnut blossom visits the mother blossom of a hickory tree the pollen of the walnut would not affect the hickory blossom, but would still have the proper effect on the first walnut mother blossom he visited.

This is how life in general is reproduced among the plants and trees. Life in the vegetable kingdom has no sense of feeling or any of the other senses, but this kind of life is still true to its own nature and is a wise thing in the plan of creation, because, since all seed will produce only plants like those from which the seed came, man can control the growth of the vegetables and fruits he needs as food. He knows when he plants corn that he will get corn in return, because perfect seed never makes a mistake. It would mix things up terribly for man if this were not so, because man might then plant one thing and find another thing growing. It would be a sad thing to plant wheat and find thistles growing.

In order that seeds may grow they must be planted under conditions that suit the kind of vegetable life in the seed. Man has to study and learn what these conditions are.

If a seed is planted too deeply the sun may not have a chance to warm the ground to that depth, and if it is planted too near the surface it may become too warm and be killed by the sun. When planted under the proper conditions the seed soon begins to grow. It grows upward toward the sun to get light and air, and it sends roots down into the ground to get food and moisture.

The life in the vegetable kingdom is soon able to take care of itself.

How Are Fishes Born?

The next step in the study of the reproduction of life brings us to the animal kingdom. The first thing we discover in this section is that in the animal kingdom father and mother natures are almost always separated. In plants and trees these parent natures are sometimes in the same flower, often separated, but on the same plant, and in other instances on different plants miles apart. What we must remember, then, is that in the case of plants it is given more or less to the chance of wind or other circumstances to bring the parent natures together.

In the animal kingdom there are a few cases where the mother and father natures are found in the same living object, as in the oyster and clam families, one of the lowest forms of animal life. These have but one of the five senses--that of feeling. This class of animals--the cold-blooded animals--includes the fishes, and in most members of this class the father and mother natures are separated and in different bodies. Step by step from now on we enter higher forms of animal life, and through each step we find a greater difference between the father and mother natures, and in the animal kingdom we speak of the father and mother natures as "_male_ and _female_." In the animal kingdom, too, what we have previously called the seed is known as the _egg_. Seeds and eggs are the same so far as their usefulness is concerned, but we say eggs in the animal kingdom to distinguish from seeds in the vegetable kingdom.

Fish have eggs, then, and it is from the eggs that little fish are born into the world and grow to be of eatable size. You recognize the eggs of the fish in the "roe," which is eaten as food. Not all fish eggs are used as food, however.

In the fish world the eggs are developed in the body of the female fish. Each little round speck in a "shad roe" is one egg, and there are many thousands in a single "roe." Each egg will produce a little fish, under favorable conditions. These eggs develop in the body of the female fish in winter. In the spring, which is the time in which most living things are born, and, therefore, the time for hatching out fish eggs, all of the fish swim from the deep water where they live in winter to the places where the water is shallow and warm, and in these shallow waters the female fish expels the eggs from her body where the sun can get at them and hatch them by warming them. After the female fish has thus laid the eggs, the male fish swims over the eggs as they lay in the water, and expels from his body over them a fluid which is white in appearance and which fertilizes the fish eggs. If any of this fluid fails to reach some of the eggs it is not possible for the sun to bring them to life.

When the eggs are laid and fertilized the mother and father fishes swim away and they never see their children or recognize them as such, even if they meet them later in life. The parent fish do not act like other fathers and mothers, and they do not need to, because as soon as a baby fish is born he is able to find his own food and needs no help from father or mother to teach him how to find it or enable him to grow into a real fish.

Of course, many of the tiny fish are eaten by other fish and not all the eggs which the mother fishes lay hatch into live fish, because, if they did, the waters would be so crowded with fish that there would not be any room for the water. A single female fish will lay millions of eggs in a year, and if each egg developed into a fish there would be far too many.

This order of animals, which includes turtles, frogs, etc., is the cold-blooded class of animal life. They have only part of the five senses. They all can feel and some of the fishes can see and hear, but a great many of them, particularly those kinds which live on the bottom of the ocean, cannot either see or hear, and some members of the fish family cannot even swim.

The thing to remember about fishes in connection with the reproduction of life is that the mother fish must select a place which is favorable to deposit the eggs, but after that her responsibility ceases. The father merely fertilizes the eggs, and then his responsibility ceases. The little fish look out for themselves as soon as they are born and never know what it is to have a father or mother to look after them.

When we study the next higher form of animal life we find that the young ones have to be looked after, and that this becomes more necessary as we ascend the scale of animal life until we reach man, the most intelligent of all animals and yet the most helpless of all at birth.

How Birds Are Taught to Fly.

The next step brings us to the birds. Before they can look after themselves the little birds must learn how to search for food and the kinds of food good for them. They have to learn the habits of their kind of life. The higher you go in the study of animal life the greater seem to be the dangers which surround the young animals and the longer it takes to teach them how to look after themselves and what to do for themselves.

The bird family includes not only the robins, larks, sparrows and pigeons, but also the ducks, geese, and chickens, etc. We are all more or less familiar with birds' eggs, and if not we know what a hen's egg looks like. The eggs of the bird family are laid in nests, which is the first sign of home building in the animal kingdom.

The birds are the first of the large class of warm-blooded animals. The egg here represents again the reproductive power. The eggs, too, form in the body of the female bird, but are laid in a nest which the parent birds build together. Now this is the first step away from the fish family. The fish looks for a suitable place to lay the eggs and then goes off and leaves them. The birds, however, have to make a nest in which to deposit the eggs. The fish, as you remember, depended upon the warm sun shining on the shallow water to hatch out the eggs, thus depending on an outside force to supply the necessary warmth. In the bird family the mother bird must cover the eggs with her own body and keep them warm until they hatch out. Then, too, the father and mother birds feed the young until they are strong enough to fly and find food for themselves, and so the mother and father birds look after their babies until they are old enough to look after themselves. When this time arrives the old birds cease to bother about the young ones altogether. The fishes never act like parents after the baby fishes are born, because the little fish are able to look after themselves right away. The parent birds are a good deal like fathers and mothers for a time, but only so long as it takes them to teach their little bird children to look out for themselves. Then they forget the children completely.

It requires but a few days and no parental care to hatch out a family of baby fishes and no attention at all after birth. It requires several weeks and much patience for the parent birds to hatch out their eggs, and it involves care and attention for several weeks to teach baby birds to take care of themselves.

This being a father or mother in the animal kingdom becomes a greater responsibility in every step as we get closer to man, and when we reach man we find him to be the most helpless offspring of all at birth, and that it takes more time, care and attention to bring up a human child to maturity than any other animal.

What Makes the Hollow Place at One End of a Boiled Egg?

This hollow place on the end of the boiled egg (sometimes it shows on the side) is the air which is put inside of the egg when it is formed so that the little chicken will have air to breathe from the time it comes to life within the egg until it becomes strong enough to break the shell and go out into the world. There is also food in the egg for him. When you boil the egg this pocket of air within the shell, which would have been used up by the chick if the egg had been set to hatch instead of being cooked for breakfast, begins to fight for its space and pushes the boiling egg back and forms the hollow place.

The purpose of the air in the egg is a good thing to remember when we come to study the higher forms of animal life from the standpoint of how they reproduce themselves.

The mammals are the next higher form of animals. The babies of this class of animals must be fed for several weeks or months before they are ready to come into the world.

A little chicken is ready to come out of the egg almost as soon as it comes to life, and, therefore, needs only a little air and food before it is strong enough to peck its way out, but the babies of mammals begin to live months before they are ready to come into the world, and they need a great deal of air and food during this time. This class includes the dogs, horses, cows, cats and all other animals in the Zoo and in the woods. The name mammals means the same as "mamma," and indicates an animal which must be fed from the body of a female mammal even after it is born.

In this class the eggs are retained within the body of the female animal instead of being laid in a nest or some other place, as in animals of lower classes, after being fertilized by the male animal, so that the baby animal may secure its food and air from within the mother's body after the life within the egg is begun.

The mother's body supplies the necessary warmth to develop the life of the little animal in the egg, just as the birds supplied this with their bodies. In the bird class it only takes a few hours to give the little bird sufficient strength to peek his way out, but in the mammal class it is a long time before the baby animal is strong enough to come out into the world, and even after it is born the

babies of mammals require a great deal of care and attention before they are able to look out for themselves. During this period the animal secures all of its food from the breast of the mother animal.

Another reason why the eggs of mammals are retained within the bodies of the females is the need for protecting the young animals from enemies. In the animal kingdom each kind of animal preys upon another kind. They attack and devour each other and are constantly in danger. If, then, mammals laid eggs in nests and sat upon them to hatch them out, the mother animals sitting on the nests would be continually in danger of attack from their enemies. They would either have to flee and subject the nest and its contents to the danger of destruction or else stay and fight, and perhaps be destroyed. But by carrying her egg within her body the mother mammal is able to move about from place to place and protect her baby.

Is Man an Animal?

Men, women and children belong to the “mammal” class of animals. The offspring of the human family is the most helpless of all animals at birth. The young of most kinds of mammals can stand on their legs shortly after being born, but the human baby requires months before it can stand up. A baby horse can also walk within a few hours, but human children do not begin to walk until they are more than a year old.

Why Cannot Babies Walk as Soon as Born?

The human baby has a great many more things to learn than a horse baby before it is safe for him to go about alone. It takes time for the brain to develop, and if a baby could walk before the brain had even partially developed it would only get into trouble.

This, then, is what we have learned about the reproduction of life and the reasons for its being different in different classes of life. First, we had the division of organic life into the vegetable and animal kingdoms. Life in the vegetable kingdom has none of the five senses, for plants cannot see, hear, feel, smell or taste. They cannot move from place to place, but remain where they grow until destroyed or removed. On the other hand, all animal life has at least one of the five senses--feeling. The oysters and clams belong to this class. Starting with this level of life in the animal kingdom we find that as we go on up through the different classes we find each class able to do things which make it superior to the class below it, until we reach the human mammal, who can do most of all. And, further, that since each class as we go up in the scale of life has greater ability to do things than the class beneath it, so in each case the task of the parents in preparing their offspring for their kind of life becomes greater, and the period during which the offspring is learning becomes longer and longer until we reach the human family, in which we find that parents have the greatest responsibility, and the children are the most helpless of all animals, but that in the final result man has a right, on account of his superior qualities, to be the ruler of the other creatures of the world.

What Are Ball Bearings?

Some years ago a gentleman in trying to find some way to reduce the friction, which is constantly developed to a certain extent, even when the axle is oiled, discovered that if between the axle and the inside of the hub a circle of steel balls were arranged, so that the hub of the wheel did not touch the axle at all, but rested on the little balls which in their turn touched the axle, that a great deal of the friction was eliminated. This proved to be a wonderful invention, and when this combination is arranged and oiled, there is hardly any friction.

Why a Gasoline Engine Goes

[Illustration: FIG. 1.]

As you know, gasoline is a very inflammable fluid, and will explode if placed too close to fire.

This explosive quality is the basic principle of the gasoline engine. By admitting a small quantity of gasoline vapor into an enclosed cylinder, and exploding it by means of an electric spark, repeating this operation continuously, the engine is given a regular rotary motion.

Look at Fig. 1. Starting from the gasoline tank, the fluid is fed into the ‘carburetor’, which is a sort of atomizer. Here the gasoline is mixed with air, and broken up into a very fine spray, in which condition it will explode readily.

The engine will not start of itself. Its fly-wheel must first be turned by hand, or by some other outside force, until the first explosion takes place. After this its action is automatic.

As shown in Fig. 1, the fly-wheel is being turned, and is drawing the piston down the cylinder, which in turn sucks gasoline vapor, (shown by little arrows) through the ‘intake valve’. This ‘intake valve’, and the ‘exhaust valve’ on the opposite side of the cylinder, are opened and closed at the proper time through the action of the gears shown in the illustration.

Passing to Fig. 2, the fly-wheel in turning has drawn the piston to its lowest point, and is now shown forcing it up the cylinder. This compresses the gasoline vapor in the cylinder to a density at which its explosion produces the greatest amount of power. The intake and exhaust valves are both closed.

~WHAT CAUSES THE EXPLOSION IN A GAS ENGINE~

Fig. 3 shows the explosion. The cylinder has been filled with compressed gas, and the piston has again started on its downward travel. The spark plug, set in the top of the cylinder, makes a spark every time an electrical current passes through it. A switch on the engine permits the current to pass to the spark plug only when the engine is at this position in its action. (Fig. 3.) The consequent explosion drives the piston downward with great force, turning the fly-wheel, which by its weight continues the rotary motion after the downward impulse of the piston has been expended.

Fig. 4 shows the fly-wheel, still turning, forcing the piston up and thus expelling the burned gases from the cylinder through the exhaust valve, held open for this purpose. From this position the engine goes again to that of Fig. 1, and through 2, 3, and 4, continuously, exploding every second revolution, and giving a regular rotary motion to the fly-wheel.

[Illustration: FIG. 2.]

[Illustration: FIG. 3.]

[Illustration: FIG. 4.]

The illustrations show a one-cylinder motor, but these engines can be built with two or more cylinders, arranged to explode at different times, thus giving very smooth action to the fly-wheel and main shaft.

Aeroplanes, almost all automobiles, various pumps and other machinery are driven by gasoline engines. The rotary motion can readily be transmitted by chains or gears to the propellor of an aeroplane or motor boat, or the wheels of an automobile. It is only in the past few years that the gasoline engine has reached its present high state of perfection.

[Illustration: HOW AUTOMOBILES HAVE IMPROVED

LEFT SIDE VIEW

RIGHT SIDE VIEW

A new exhibit in the Smithsonian Institute, officially known as “Exhibit Number 56,860,” is attracting a great deal of attention from visitors to the National Museum. It consists of a complete Haynes six-cylinder unit power plant, and has been given a position at the side of the original Haynes “horseless carriage,” where the striking contrast shows the remarkable improvement that has been made in motor design and construction during the past twenty-two years.

The most important features of the power plant are shown clearly and comprehensively by having sections cut away from the various parts, so that the visitors to the Institute are enabled to see the mechanical construction, and the relation of the component devices.

On the right side of the engine, the intake and exhaust manifolds are shown in their natural position. A full vertical section of the Stromberg carburetor gives a good idea of how the gasoline is mixed with the air and supplied to the cylinders. The Leece-Neville generator has its casing cut away to give a view of the windings and cores. Numerous windows have been cut into the crankcase to disclose the crankshaft construction and the oil reservoir. The transmission gears are also shown in this manner.

Most of the electrical equipment is shown clearly on the left side of the motor. Here an interesting feature is the full vertical section of the American Simms high-tension dual magneto. A half section has been removed from the rear cylinder, and the piston as well, to give a glimpse of the interior construction. A large portion of the Leece-Neville starting motor casing has been cut away. The cover-plate on the switch controlling the starting motor has been replaced with a glass cover to display the method of completing the circuit from the battery to the motor. A skeleton selector switch is mounted at the rear of the transmission case, instead of its usual position on the steering wheel. The electric gear-shifting mechanism is made visible by using a glass plate for the top cover-plate on the transmission.]

Why Does the Heart Beat When the Brain Is Asleep?

Under ordinary conditions the heart beats are controlled by certain nerve cells which are located within the heart itself, and these cause the heart to beat even while the brain is asleep. This explains why the heart beats when the brain is asleep, and the fact that the brain when asleep does not exercise its functions, shows how necessary this arrangement and the control of ordinary heart beats is. If this were not so, we should not be able to live while asleep. It is just like the management of a great business in this sense. The general manager of a great business has control of the entire works, but there are occasions when he must be thinking of only one thing in connection with the business, and so he must have his organization so complete, that the parts which he cannot be thinking about at the time will do their work just the same. So he surrounds himself with competent assistants, who look after certain departments while he is busy or away or asleep, and if anything goes wrong while he is away, he calls on special forces to set things right. Now, the brain is the general manager of the whole body and has these nerve cells in the heart as a sort of

assistant manager to look after the heart beats in ordinary conditions, and to keep the heart going while he is asleep. But, by reason of his office as general manager, the brain has a special way of sending orders to the heart through special nerves which run from the brain down each side of the neck to the heart. There are two pairs of these special nerves. One pair, if set in motion, will make the heart beat faster, and the other pair will make the heart beat more slowly.

Why Do Our Hearts Beat Faster When We Are Running?

When you start running, the brain knows at once that your legs and other parts of the body will need more blood to keep them going, and so the brain sends down orders through his special nerves which make the heart beat faster, to get busy, and they do. Then when you stop running, your heart is beating faster than necessary--there is really an oversupply of blood being pumped through your system for the time being, and that makes you uncomfortable, until the brain sends word through the other set of nerves to the heart to slow down the heart beat. It is better to stop running gradually, to give the heart a chance to get back to its normal beat gradually also.

Why Do I Get Out of Breath When Running?

This is also caused by your brain in its efforts to keep up your supply of good blood. We breathe to take air into the lungs, where the blood which has once been through the arteries and comes back on its return trip to the heart, is exposed to the air in the lungs, before going back into the heart. The air which we take into our lungs purifies the once used blood and makes it into good blood again. When you run the heart pumps blood into your arteries faster to enable you to run. Thus also, the arteries send much more blood back to the heart through the veins, and this must be purified by the lungs before going back into the heart. To attend to purifying this extra amount of spoiled blood the lungs need more air, and thus you are made to breathe in more air for the purpose. Unless you are in good training--your wind in good condition as we say--it is almost impossible for you to supply the lungs with enough air for the purpose, but whether you can do it or not, the lungs call upon you for more air, and cause you to try to get it, and that is what makes you get out of breath.

Why Does My Heart Beat Faster When I Am Scared?

The natural tendency of a scared creature is to run or fly. The effect of being scared has the same effect on the brain that your starting to run has. The brain is always as quick as you are, and knowing that when you are scared your actual or natural inclination is to run, it is merely getting you in shape so that you can move or run fast.

Why Does Cold Make Our Hands Blue?

Your hands appear blue when cold because the veins which are near the surface are filled with impure blood which is purplish in color. Your hands become cold because there is not sufficient circulation of warm red blood going on to keep them warm. The blood in circulating through your body sends warm red blood through the arteries, and this is returned to the heart through the lungs by way of the veins. The veins carry only used-up blood or what is left of the good red blood when the arteries are through with it. Its color is a purplish blue.

When your hands are blue it means that circulation of good red blood has practically stopped--the red blood is not flowing from the heart through the arteries in sufficient quantity and there is no color in the arteries, as the blood from the arteries has practically all gone into the veins. The veins are full to purplish blue blood, and this makes the hands look blue, because there are a great many veins in the hands close to the surface.

Why Do I Get Red in the Face?

Now, when you rub your cold blue hands together, you start the circulation going again, and that brings the red blood into the arteries, giving you the healthy red color again. When you run hard to get red in the face because you are causing an unusual amount of red blood to flow through your whole body by your violent exercise. Some people with an extraordinary amount of circulation are red in the face all the time. This is because of the presence of a great deal of blood in the arteries, or because the walls of their arteries are so much thinner than others that the red blood shows through more easily.

Is Yawning Infectious?

Yawning is infectious to the extent that other habits are. The desire to yawn which comes to us when we see some one else does so comes under the heading of suggestion. The power of suggestion is greater than many of us realize. We are great imitators of each other. When one of us is downhearted, we are apt to become happy and glad simply by being with other people who are happy and glad. If enough people one at a time tell a perfectly well man that he looks sick, he will actually feel ill, provided he does not suspect a game is being played on him. So a good actor carries his audience with him. He can make them laugh or cry almost at will, and if he yawns, his audience will begin yawning.

Often, however, there is no acting connected with the yawning of the first person. Then the yawn is caused because the person is not sending enough good air into the lungs for purifying the blood, and the yawn is only nature's way of making us take an exceptionally deep breath of air in at one time. This lack of sufficient good air in the lungs may not be due to the poor breathing, but to the amount of bad air in the room. In such cases it is quite likely that other people in the room yawn when one of them starts it because they all begin to feel the need of more good air at about the same time.

What Makes Me Want to Stretch?

The necessity or desire to stretch comes to us because certain parts of the body are not receiving the proper amount of blood circulation and it is these parts that we stretch at such times. If you have ever been to a ball game, you know, of course, that it has become customary for the crowd, no matter how large, to stretch its legs and arms during the last half of the seventh inning. In fact, that has come to be a fixture at ball games and is universally known as the "stretch inning." Now, it is not so much the result of a desire to encourage the home team as the natural following out of nature's laws that originally started this practice. The end of the seventh inning at a ball game generally means that the crowd has been sitting quite still for the greater part of an hour and a half, just long enough for the circulation to become poor in parts of the body, and the custom of stretching at a ball game thus comes from the necessity of getting a little more speed into the action of the heart to increase the blood supply.

In other words, the stretching constitutes a mild form of exercise. You will notice the ball players themselves do not stretch themselves in the last half of the seventh inning. They are getting enough exercise without that.

It is natural, however, for us to stretch as we wake up from sleep after having lain quietly in one position for one or more hours. It is nature's way of causing the heart to work faster.

What Happens When I Stretch?

What happens is simply this. When you stretch your arms and legs, you squeeze the arteries and veins which are a part of your arms and legs, much as happens when you pull on a piece of rubber tubing. The tubing becomes flat instead of perfectly round, and it is not so easy to send water through a flat tube as through a round one. Just so with the heart. It is the heart's business to send blood through the arteries at all times, and when you make them flat the heart's job becomes just a little harder, and it goes to work beating just a little faster to overcome this extra difficulty. By that time you are through stretching and the heart is busy pumping blood a little faster than ordinarily, and that is what makes you feel so good after you have stretched.

Why Can We Think of Only One Thing at a Time?

If you are asking the question intelligently, you must know that to think means to concentrate, and in that sense we can only think of one thing at a time, because it takes all of that part of the brain which is used for thinking for just one thing. To give close attention to any one subject means to turn the entire brain force practically in one direction. To let other things pass through the mind at the same time may appear not to interfere with the one thought, but they do, and our conclusions suffer accordingly.

You can be doing something with one part of your body, while engaged in thinking of one thing, but only such things as are more or less mechanical as the result of habit, such as walking, or moving the arms--things which the parts have done so often that actual attention by the brain is not absolutely essential. Take for instance, the fact that a man in deep thought on one subject will sometimes walk up and down the room or along the sidewalk. He can do this walking and still think concentratedly, but if he stubs his toe on the leg of a chair or on a rough place in the walk, his thought is broken, because the brain immediately takes itself out of the thought and pays its attention to the toe that was stubbed.

Why Do I Turn White When Scared?

Simply because, when you are scared or frightened, the blood almost leaves your face entirely. Under normal conditions, the red blood which is flowing through the arteries of your face, gives the face a reddish tinge, and your face becomes white when you are frightened, because then the blood leaves the face. It is quite singular, but when you are really frightened, whatever the cause may be, the human system receives such a shock that the heart just about stops beating all together. When your heart stops beating of course the flow of the blood from the heart stops and then there is no supply of fresh red blood coming through the arteries under the skin of your face. Therefore you look white--the color your face would be if no blood ever flowed through your arteries and veins. Some people have faces so white they look as though they were scared all the time. This is not because they have no blood flowing through the veins and arteries in their faces, but because their supply of blood is less than other peoples, and sometimes because the walls of their arteries and veins are much thicker than the average that the color of the blood does not show through. There are also many people who have so much blood in their systems all the time, and the walls of whose arteries are so thin, that they look at all times as though they might be blushing.

What Makes Me Blush?

Anything that will make your heart send an extra supply of blood into the arteries and veins which supply your face with blood, will make you blush. Embarrassment will do this. So will anger generally, although sometimes people get so angry that the blood is driven out of their faces. In this case they are so angry that their heart has stopped beating, practically.

What Occurs When We Think?

When we think the mind is acting on sensations; it is receiving, in conjunction with memories of sensations it has previously received. Sensations as they reach the mind arouse the mind to activity and, as soon as the sensation is received, the mind begins to compare the new sensation with sensations received at previous times, and by putting things together reaches a conclusion.

When you are thinking you are really trying to call upon memory to help you. You know the thought of one thing calls up another, and this leads to something else. This association of ideas is the faculty which enables us to think consecutively and accurately. It is the business of the mind to receive the sensations that enter it and arrange them in their proper places. That memory of past sensations is the important part of thinking, is proven by the fact that when we have forgotten a thing we are unable to think what it was.

Can Animals Think?

For this reason if animals have memory they should be able to think. It is now believed that many animals have to a certain extent the power to remember.

A dog will recognize his master even though he has not seen him for years. We might think he does this by his highly developed power of smell, but if his master has come from a direction opposite to that from which the dog first sees him, he could not have tracked him by his smell. A dog will recognize his master from quite a distance, so he must have to a certain extent the ability to remember or the power of association of ideas, which amounts to the same thing. Again, a horse that once belonged to the fire department, even though now hitched to a milk wagon, will have the impulse to run to the fire when he hears the fire gong. And an old war horse will prick up his ears as he used to when he hears the bugle call.

Why Do I Sneeze?

You sneeze sometimes when you look up at the sun or at a bright light. There does not seem to be any real good explanation of why looking at a bright light should make you sneeze. It is due to the connection there is between the nerves of the eyes and the nose. You generally blink if you look at a bright light suddenly, and the blinking process stirs the nerves inside of the nose to make you sneeze.

You know, of course, that the start of the sneeze is inside of your nose. The nose is, besides being the organ of smell, the channel through which we take air into the lungs, when we breathe properly. The nose is lined with membranes, back of which are a net of

very small nerves which are extremely sensitive. The membranes are placed there to catch and hold the impure particles of matter which come into the nose when we take in a breath of air, and sneezing is only one effective way of cleaning out the nose. It is brought on only when some particularly difficult job of nose-cleaning has to be done. Pepper up the nose will make you sneeze quickly, because pepper produces a very great irritation inside the nose, and the nose goes to work at once to get rid of it in the quickest possible manner as soon as the pepper comes in. Other things have the same effect. Sometimes a cold in the head causes you to sneeze. The sneeze in that event is merely nature's effort to clean out the nose when other efforts have failed.

There are many suggestions for stopping a sneeze before it takes place, after you feel it coming on, such as putting the finger on each side of the nose, and many others. But a half sneeze does not remove the cause of the sneeze, so it is much better to sneeze it out, and many people enjoy the after effects of sneezing so much that they take snuff into the nose to produce it.

What Happens When I Swallow?

The muscles of your throat act in the form of a ring when food passes into your throat. The food does not drop directly into your stomach. In other words, the action is not quite the same as when you drop a stone out of the window. When you do the latter, the stone hits the sidewalk or whatever is below at the time, with a smash. It would hardly do to have our food drop into the stomach, so the muscles of the throat are arranged to contract in rings which push or squeeze the food downward, and the food is passed from one ring of muscles to the other. It is just like pushing a ball down into the foot of a stocking that is apparently too small for it to drop down. You put the ball in the top of the stocking and then by making a ring of your fingers around the stocking you can push the ball down. When you swallow, you start the muscles of your throat to making these rings. The upper ring squeezes the food on to the ring below it and so on down to the stomach.

What Makes the Lump Come In My Throat When I Cry?

The "lump" which comes up into your throat when you cry is caused by a sort of paralysis of the rings of muscles in your throat. The muscles of your throat can make these rings or waves upward also, but it is more difficult upward than downward--probably because of lack of practice, as we say. When you have put something into your stomach that makes you sick and causes you to vomit, the throat muscles take the matter from your stomach and bring it back to the mouth in the same way, except, of course, that this action begins at the bottom.

Sometimes when you cry, or lose control of yourself in some other way (you know, of course, that in crying you always lose control of yourself, don't you) practically the same effect is produced as when you have something in your stomach that should come out. Crying, or the thing that happens sometimes when we cry, makes the throat muscles act just as if we were vomiting, and as the action is an unnatural one, when the ring or wave reaches the top of the throat, we feel the lump or ball as we call it. We feel the lump because the throat has been made to go through the motion of eliminating something in an unnatural way, just as your arm will hurt if you pretend to have a ball or a stone in it, and in throwing the imaginary ball or stone, you put the same force into your movements as you would if you had an actual ball or stone in your hand and were seeing how far you could throw it.

Why Do We Stop Growing?

We eventually stop growing because certain of the cells of the body lose their ability of increasing in size and producing other cells. It is one of the marvels of the construction of the human body that this is so and one of the wisest provisions also. At first the cells of the body crave lots of food and increase in size, divide and then the parts go on growing until they become of a certain size, when they again divide and each part goes on growing, etc., and thus we grow. A growing boy needs more fond than a mature man, because he needs some of it to grow with, while the man only has to keep what growth he has going, i. e., alive.

We say this limit of growth is a wise provision of nature because if there were no limit to the size we might become, we would not know how large to build houses, barns, etc., or else we would have to build them so large to start with that we would be lost in them for a long time. We would constantly be forced to change these things and there would be no basis to reckon from. Dogs might be as big as elephants and then they would be of no use to us, or of what use would a dog as big as an elephant be to a boy of five years. You see it would not do at all to have this rule changed.

Why Do We Grow Aged?

We age directly in accordance with the lives we lead. You can bend a wire back and forth a number of times at the same point without breaking it, but eventually it will break. Just so with the human body. You can use each part of it for its own purposes a number of times, but eventually the break will come. Or, you can fail to make a part of it perform its regular functions, and it will die--the break will come. The human body is the most wonderful machine in the world, but even it will eventually wear out. Every time you move your arm, leg or some other part of your body, you destroy some tissues. The body replenishes and builds up those tissues again for a certain time. When you bend a joint in your body, the body oils the joint naturally, but as you grow older, or rather, as you use the different parts of your body more and more, it brings nearer always the time, when the body cannot, of its own accord, build up again the tissues you have destroyed. That is why some people become very old at forty and others are still comparatively young at seventy. It requires a great deal of care and attention and the elimination of all abuse of the body to keep us young when we are old. The use of drink, lack of sufficient sleep and other abuses prevent the body from restoring the tissues which have been destroyed. Worry and sorrow age us very rapidly, because these things affect the nerves. If the nerves are not quiet we cannot get any rest and without rest we grow old very rapidly.

What Causes Wrinkles?

Wrinkles come to us in several ways. An easy way to cause wrinkles is to scowl and frown and get into the habit of doing this. When you scowl or frown you pucker up the skin on your forehead into wrinkles and if you continue the habit the skin on your forehead makes the wrinkles permanent. You have given your skin the wrinkle habit. This acts just the same way as your arm would, if you tied it up in a sling and held it close to your side for a very long time--a number of weeks. When you took the sling off you would find your arm useless--a dead arm. It had developed the habit of doing nothing.

In old people, however, wrinkles come more naturally. There it is the case of the skin not receiving the proper nourishment and attention to keep the circulation of the blood right. When people become old they are apt to lose the fat which has accumulated under their skins. If they had taken just the right amount of exercise all of their lives and kept their circulation perfect in all parts of the body, there would have been no fat there. But when the fat accumulates, it makes the skin grow larger, and then when the fat disappears and people get thin again, the skin is too large and makes the wrinkles.

Does Thunder Sour Milk?

Milk will sour in any kind of warm and moist temperature and, because just before and during a thunderstorm the air is generally quite warm and moist, it is only natural that it should turn sour. It is wrong, however, to say or think that thunder makes milk sour. Thunder is only a noise and noise cannot do anything but make itself heard. The fact that it is generally warm and moist, however, when it thunders, coupled with the fact that these conditions of the air sour milk very rapidly, have led people to connect the two in their minds and caused them to fall into the error of believing that the thunder is responsible for the change in the milk.

What Makes the Rings in the Water When I Throw a Stone Into It?

Every movement has a beginning. When a movement on the earth is once started it keeps on going until something stops it. If nothing stops it it will go on forever.

When you shout you start air waves going in every direction, which keeps on going until stopped by something which has the power to break up their waves.

When you throw a stone into the ocean you start a series of ripples or waves which spread out in every direction and if you dropped your stone into the exact middle of the ocean--half way from each side--in a perfectly calm sea undisturbed by other forces, your ring of ripples would go on getting larger until it landed on the beach or shore on each side of the ocean at the exactly the same time and there the beach or shore would stop it.

The original ring of ripples is caused by the fact that when you drop a stone into the water it disturbs the water where it goes in and the water moves away from the stone to the sides, and as the stone goes down, over and up above it, and the whole body of the water is disturbed in such a way that makes the ripple appear on the surface and spread out in every direction. As the stone goes down into the water further and further the disturbance is repeated and ring after ring appears on the surface.

Of course there are many disturbances in the water at all times. Many things may happen to break up your little ring of ripples before they touch the sides of the ocean--a ship--a fish--the wind--or one of many other things, and because this is true you would have difficulty in sending the waves made by your little pebble across the ocean, but you can take a dishpan from the kitchen and after filling it with water drop pebbles into it as nearly the middle as possible, and you will see the ripples or waves your pebble makes spread out from the point where the pebble entered the water in all directions.

Why Are There Many Languages?

Different languages developed in different parts of the world because there was no inter-communication between people in different communities, and each was really developing a language for itself. In doing so they developed their language without knowing that other communities were working out the same problems for themselves. So they first developed their own sign and gesture language and later on their word or sound language and kept on using it. While they may thus have developed the use of some of the same signs and sounds or combination of sounds to express one thing perfectly understandable to themselves, these sounds or combinations of sounds might mean something entirely different to another community, where that particular sound or combination of sounds may have been hit upon to mean something entirely different.

Of course, not all languages were developed in this way. There are, you know, a great many languages used in the world. Some of them are offshoots of others, where part of a community moved to another part of the world, taking their language with them, but developing it further along new lines, and using new combinations of sounds for new words. Then also, there are many words which mean the same thing in different languages and are spoken with practically the same sounds. This is due to the movement of people from one nation to another and bringing their own words with them, so to speak. In many instances a stranger would come to another nation, and use his own word for expressing a certain thing and that would eventually be taken up and used as a better word, and the old word dropped. It is strange that this should be true, but this accounts for the fact that many words are the same in sound and meaning in numerous languages.

What Makes a Match Light When We Strike It?

The match lights when we rub it along a rough substance, because the rubbing produces sufficient heat on the end of the match to set fire to the head, as we call it, which is made of chemicals that light more easily than the stick of wood, which is the rest of the match. The fire thus started is hot enough and burns long enough to set fire to the wooden part of the match.

To explain this more fully, let me say this. Rub your finger quickly along your coat sleeve or along the seat of your trousers, long a favorite place for men to strike matches, pretending that your finger is a match. You find the end of your finger becomes warm, don’t you? Not warm enough to set your finger on fire, of course, but if you had the same combination of chemicals on the end of your finger that there is on the match, you would set the chemicals afire and this would burn your finger, just as it sets fire to the wooden part of the match.

It took a great many years to discover the combination of chemicals of which the head of the match is made. Before that discovery was made it was far from easy to light the light in the evening as it is now. It must have been a serious thing to let the fire go out in the furnace in those days.

What Makes the Kettle Whistle?

The kettle whistles only when the water boils and the steam or gas which is the form the water turns into when boiling is trying to escape through the spout of the kettle. You see, when the water starts boiling, the inside of the kettle is at once filled with steam and more is coming out of the water all the time. This steam must get out some way, so it rushes for the spout of the kettle, and because so much of it is trying to get out of a comparatively small opening at once there is quite a pressure and this results in making the whistle out of the spout of the kettle. It is just the same process as when you whistle yourself. To whistle you fill your mouth with air and force it out through your lips, which you have closed excepting for a small opening, by the pressure you can bring to bear with the roof and sides of your mouth, and if you have learned to make your lips into the proper shape and apply the pressure steadily you can sound a very long note and make different notes by making the opening in your lips large or small. The kettle spout has only one size of opening so the sound is practically the same at all times though louder at sometimes than at others. This is caused by the varying pressure at which the steam in the kettle is being forced out.

What Makes the Water From a Fountain Shoot Into the Air?

The water from the fountain shoots into the air because water anywhere will run down if given a chance. To produce a fountain you must have a source of water supply for the fountain which is higher than the openings of the fountain out of which the water shoots. The water comes out of the holes in the fountain for the same reason that it comes out of the faucet in the kitchen or bath room. In the latter case the water comes from the waterworks reservoir in which the level of the water is much higher than the opening in the faucet in your home. Being higher the water in the reservoir is trying to get away through the pipes all the time and all the pipes leading from the reservoir are full of this water trying to get away. Just as soon as you turn the valve in the faucet the water comes out and runs down into the bowl.

If you were to turn the opening of the faucet up instead of down as it is, the water would shoot up instead of down. Not very much, it is true, but it would act much like the water from the fountain. The reason it does not shoot up high in the air like a fountain is because the opening in the faucet is the same size as the opening in the little pipe which leads the water from the street into the house. If you would turn the opening of the faucet up and attach to it a pipe which made the opening much smaller (the size of the opening in the fountains), you would see the water shoot into the air just as it does from the fountain. When you reduce the size of the opening you increase the pressure of the water coming from the pipes in proportion to the reduction you have made in the size of the opening.

Water from the fountain will not, however, shoot as high as the level of the water in the reservoir because, as soon as it leaves the pipes, it encounters the pressure of the air outside the pipes and the law of gravitation which pulls all things toward the center of the earth.

It is not natural for water to shoot into the air as it does in a fountain. The only way water can go naturally is down, and it only goes up a little way from a fountain because of the pressure of the water in the pipes behind the openings in the pipes in the fountain.

What Keeps a Balloon Up?

A balloon stays up in the air, because of the air in it, together with the weight of the balloon, is less than an equal bulk of the air in which it floats.

In former days of ballooning the balloons were filled with hot air and were then found to rise and stay up until the air inside of the balloon became of the same temperature as that in which it floated. When this stage was reached, the balloon itself would fall because the material of which it was made was denser than air.

Today balloonists fill their balloons with gas which is lighter than air, even when as cool as the air in which they rise and are thus able to stay up a long time.

You, of course, have seen many of the red, white and blue paper balloons which are sent up on the Fourth of July. You will remember that father, or whoever it is that is sending them up, lights the oil-soaked knot of cloth that is attached to the balloon immediately below the opening at the bottom. He first lights this and then holds the balloon for a time with his hands.

Soon, however, you will remember that the balloon starts upward with father still holding it. This is because the air inside the balloon is becoming heated. You will notice also that at first he has to hold out the sides of the top of the balloon with his hands or has some one help him do this, but that even so the balloon does not stand out round and full as it should. When the balloon starts to rise, however, you will notice that it is round and full. This is because the air in the balloon has become heated and is expanding. Soon the balloon is tugging to get away and father lets go and it rises and sails away with the wind. As long as the fire below it burns, and if the wind does not upset it so as to make the paper part catch fire, the balloon will stay up; but, when the fire burns out, the balloon will come down.

The balloon merely rises because the air inside, and held there by the covering of the balloon, is warmer air and lighter than the air on the outside.

Why Did People of Long Ago Live Longer Than We Do Now?

When reading of people who lived long years ago and especially when reading about the length of their lives, we are told that in the old days people lived longer than they do now. Some of the early historical records speak of single individuals who lived hundreds of years. There is great doubt as to whether these statements are founded on fact. In thinking about this we must first take into consideration that these records of long ages were recorded at a time when man had no accurate ideas of the actual passage of long periods of time such as a year. They did not have our calendar as a basis for figuring at all. Learned men now tell us that the actual age of men who lived at the time these records of great ages were recorded probably lived shorter lives than we do now, and that what they record as a period of one year was probably a much shorter period than one year.

It is true beyond the question of a doubt that the people of today live longer on the average than people who lived ten, twenty or more years ago.

In other words, the average period of life has increased steadily. This is due to the fact that we have taken great care of our bodies; have improved the conditions in which we live, and made them more sanitary; have learned to fight and check and eradicate diseases, which only a few years ago we could not prevent people dying of when they once contracted them, and we know from the records which we keep that actually people live longer on the average today than only a few years ago, and it is safe to say that they live longer now on the average than at any time in the world's history.

Is There a Reason for Everything?

The world is so constructed that there must be a reason or cause for everything. There are so many forces in the world that man has not yet been able to locate the original cause of every one of them. Concerning other things, he sees the effects without having any knowledge of the forces which are their cause. Other things he has never even bothered to inquire about, but simply takes them for granted. But every force, which means, of course, everything in the world, must have had a beginning and therefore something or a combination of things must have caused it to begin, and the thing or things that caused it to be is the reason for its being. Every little while someone makes a discovery of some new force, and then we suddenly realize that this force has been in existence all the time although not known to man, and we discover through this the reason for many other things being as they are.

The other thing or side of the question is also true. We cannot have a cause without an effect. You cannot do anything without causing something to happen and producing an effect on one or more other objects either animate or inanimate. You cannot move your hand without creating some disturbance in the air. When you make a noise, low or loud, you produce sound waves. When you burn a stick of wood, you create smoke, ashes and gases of various kinds. You change the whole nature of what was the piece of wood, and yet no particle of what made the stick of wood is ever destroyed or lost, but appears in some other thing in the air or on or in the earth.

What Makes an Echo?

An echo is caused when the waves of air which you create when you shout are thrown back again when they are stopped by something they encounter and are turned back without changing their shape. Any kind of a sound wave will make an echo in this way.

You see, you can have no sound of any kind without sound waves. You could not make a sound if there were no air. Now, when you shout, you start a series of sound waves that go out from you in every direction and they spread away from you in circles just like the rings of ripples that are caused when you drop a stone into a pool of water. You can prove this to yourself easily by having one, two, three or more of your friends stand around you in a large circle. You can place them as far away from you as your shout can be heard if you wish. When you shout, each of your friends will hear the shout at the same time, provided, of course, they are at equal distances from you.

Sometimes these sound waves as they go away from you in circles strike objects that turn the waves back unbroken just as they came to them. The waves will bounce back just like a rubber ball from a wall against which it has been thrown and this is the echo. However, some things that the sound waves strike break up these waves entirely and others partially.

No doubt you have sometimes noticed when you shout you hear a distinct echo and that at other times, standing in the same place, you cannot hear any echo, although you shout in the same way. This is explained by the fact that at times conditions of the air are such that no echo is produced while at other times a perfect echo results.

What is a Whispering Gallery?

The possibilities of an echo have to be taken into account by the architects and builders of all public buildings, such as theaters, halls and churches, where anyone is to speak or entertain others. Unless they are very careful the walls and ceilings may be so arranged that when any one sings or speaks in the room, there is such an echo that it interferes with the music or speaking. It sometimes happens also that through some peculiarity in which the walls and ceiling of a building are constructed there will be certain places in the room where an echo can be heard, even a whisper, and which cannot be heard in other parts of the room at all. This is likely to occur in rooms where there is a dome-shaped ceiling. There will be certain spots in the room hundreds of feet apart, where if you stand on one spot and another person is on another definite spot clear across the room, the tiniest whisper can be heard, while the people in between cannot hear at all. This is called a whispering gallery. Of course, loud talking would produce the same effect. A whispering gallery is a gallery with an echo which can be heard from certain positions. There are a number of famous whispering galleries of the world. In the room beneath the great dome of our Capitol at Washington is an almost perfect whispering gallery. There are quite a number of points at which you can stand and hear the whispers across the room which is more than a hundred feet. These whispering galleries come accidentally, of course. It would be difficult to deliberately construct a building in such a way as to produce a whispering gallery.

Why Do We Get a Bump Instead of a Dent When We Knock Our Heads?

When you knock your head against a sharp corner, or if some one hits you on the head with anything with a sharp edge, you do receive a dent in your head, but it does not last. In other words, the head has one of the qualities of a rubber ball. You can press your finger against the sides of the rubber ball and push it in, but when you take your finger off the ball resumes its shape. Just so with your head--it resumes its shape after a blow.
